

# Epigenomic Diversity in a Global Collection of *Arabidopsis thaliana* Accessions

## Graphical Abstract

## Highlights

- Transcriptomes and methylomes from over 1,000 *Arabidopsis* accessions
- >25% of genes show either gene-body or TE-like methylation states
- Maximal sequence and methylation variation seen at immunity loci
- Methylation strongly correlated with climate of origins and *trans*-acting variants

## SUMMARY

The epigenome orchestrates genome accessibility, functionality, and three-dimensional structure. Because epigenetic variation can impact transcription and thus phenotypes, it may contribute to adaptation. Here, we report 1,107 high-quality single-base resolution methylomes and 1,203 transcriptomes from the 1001 Genomes collection of *Arabidopsis thaliana*. Although the genetic basis of methylation variation is highly complex, geographic origin is a major predictor of genome-wide DNA methylation levels and of altered gene expression caused by epialleles. Comparison to cistrome and epicistrome datasets identifies associations between transcription factor binding sites, methylation, nucleotide variation, and co-expression modules. Physical maps for nine of the most diverse genomes reveal how transposons and other structural variants shape the epigenome, with dramatic effects on immunity genes. The 1001 Epigenomes Project provides a comprehensive resource for understanding how variation in DNA methylation contributes to molecular and non-molecular phenotypes in natural populations of the most studied model plant.

## INTRODUCTION

Cytosine methylation and histone modification are epigenomic marks with effects on the activity of transposable elements (TEs; all abbreviations are listed in Table S1), transcription of

genes, and formation of heterochromatin. In plants, DNA methylation occurs in the symmetric contexts CG and CHG (H = C, A, or T), and the asymmetric context CHH (Law and Jacobsen, 2010). CG methylation is propagated through a simple copy mechanism during DNA replication, whereas CHG and CHH methylation are maintained by self-reinforcing loops (Kawashima and Berger, 2014). Although changes in DNA methylation may arise spontaneously (Becker et al., 2011; Schmitz et al., 2011), genetic and environmental factors are almost certainly more important. The genetic basis of DNA methylation variation includes structural variations such as TE insertions/deletions (indels), chromosome rearrangements, and mutations in methylation factors (Pecinka et al., 2013), whereas important environmental conditions include temperature and other stresses (Dowen et al., 2012; Dubin et al., 2015; Secco et al., 2015).

It has been proposed that, as sessile organisms that can persist in the same location for a long time, plants may be particularly likely to exploit DNA methylation for rapid adaptation to changing environments. DNA methylation can affect gene expression and cause visible phenotypes (Pecinka et al., 2013; Schmitz and Ecker, 2012) and measurable variation in adaptive traits (Cortijo et al., 2014; Johannes et al., 2009; Kooke et al., 2015). Therefore, cataloging variation in DNA methylation, transcriptomes, as well as genome structural variation in natural populations is a prerequisite for understanding the role of natural epigenetic variations in adaptation to local environments.

We have previously described base-resolution DNA methylomes of two medium-sized sets of *Arabidopsis thaliana* accessions: a global set of 144 accessions and a focused regional set of 150 Swedish accessions (Schmitz et al., 2013; Dubin et al., 2015). These and related studies (Hagmann et al., 2015; Pignatta et al., 2014; Shen et al., 2014; Vaughn et al., 2007) have provided initial evidence for the interplay of genetic and

**Figure 1. Origins of 1,028 Accessions Included in the 1001 Epigenomes Project, Methylocenes, and Transcriptomes.**

(A) Overlap between accessions used in the 1001 genomes, methylocenes, and transcriptomes projects. All are included in the initial selection of 1,227 accessions.

(B) Overlap with published population methylocene studies (Dubin et al., 2015; Hagmann et al., 2015; Schmitz et al., 2013).

(C) Sample types for the 1,028 accessions. Plants were grown and sequenced at the Salk, GMI, or MPI. Since more than one sample type was analyzed for some accessions, there were 1,107 methylocenes from 1,028 accessions and 1,203 transcriptomes from 998 accessions. Transcriptomes were sequenced mainly on the Illumina platform and partly with SOLiD platform (CS). Growth temperatures are in parentheses. a.t., ambient temperature 22°C.

See also Figures S1 and Tables S2 and S3.

epigenetic variation in shaping molecular and non-molecular phenotypes. Leveraging the expanded analysis of sequence variations in the genomes of 1,135 natural accessions (The 1001 Genomes Consortium, 2016), here we describe results from the accompanying 1001 Epigenomes Project, with 1,107 methylocenes from 1,028 accessions and 1,203 transcriptomes from 998 accessions. Additionally, we analyzed optical genome maps from nine accessions to infer how structural variations in the genome shape the methylocene and transcriptome. The full representation of epigenomic diversity in *A. thaliana* will accelerate studies in this model plant to provide insight into general principles of adaptive variation.

## RESULTS AND DISCUSSION

### The Dataset

The 1001 Epigenomes Project reports on 1,227 worldwide *A. thaliana* accessions selected based on their genetic and geographic diversity. We generated high-quality base-resolution methylocenes for 1,028 accessions and transcriptomes for 998 accessions (Figure 1A). Of these, 866 accessions have both methylocenes and transcriptomes from rosette leaves, as well as SNP and small indel data from the 1001 Genomes Project (The 1001 Genomes Consortium, 2016; Figure 1A). The methylocenes for 745 accessions have not been reported before (Figure 1B). Overall, the 1001 Epigenomes Project provides 1,107 methylocenes and 1,203 transcriptomes (Figures 1C and 1D).

### The Methylocenes

MethylC-seq bisulfite sequencing reads were mapped against individual pseudo-reference genomes generated for each accession by substituting SNPs and short deletions (up to 40 bp) in the Col-0 reference genome sequence (TAIR10). On average, 88% of each genome was covered by unique reads, with 8.4× strand-specific coverage (Figure S1A; Table S2).

Over a third of all cytosines (14,799,349) were methylated in at least one accession (Figure S1B). On average, the genome-wide weighted methylation level was 5.8% (Figure S1E; Table S2). 78% (11,554,831) of methylated cytosines (mC) were differentially methylated across accessions (dmCs; Figures S1C and S1D). Among dmCs epi-genotyped in at least 110 methylocenes (10% of analyzed methylocenes), singleton epi-alleles (in which only one accession was methylated or unmethylated) accounted for 5.4% dmCs in CG context, 6.7% in CHG context, and 17.0% in CHH context. In terms of chromosomal distribution, mC and dmC in all contexts were enriched in the pericentromere while mCG and dmCG have higher frequencies along chromosome arms, as expected for CG gene body methylation (gbM; Schmitz et al., 2013).

We collapsed dmCs within 200 bp blocks and identified 22,060 differentially methylated regions (DMRs) that covered 45 Mb (38%) of the reference genome. We classified them into mutually exclusive categories: CG-DMRs (differentially methylated only in the CG context), CH-DMRs (in CHG and/or CHH context), and C-DMRs (in CG and CHG and/or CHH context; Figures S1G–S1J; Table S3). CG-DMRs generally overlapped with genes, reflecting variable CG gbM (Figures S1K and S1L). About half of CH-DMRs overlapped with TEs and 35% did not overlap with any annotated regions (Figures S1K and S1L). C-DMRs overlapped with genes and TEs (Figures S1K and S1L). DMR distribution reflects the general chromosomal distribution of the overlapping genomic features (Figure S1F). Gene Ontology (GO) enrichment analysis revealed that genes for housekeeping processes, such as protein-localization/transport-related genes and metabolism, were enriched in CG-DMRs (Figure S1M), whereas CH-DMRs showed no enriched GO terms. In line with previous results (Schmitz et al., 2013), genes that had particularly variable expression levels across tissues or environments in the reference accession, including disease resistance genes, were enriched in C-DMRs (Figure S1N), suggesting that C-DMRs

- (A) Correlation between the number of gene-body-methylated (gbM) genes (x axis) and their average CG methylation levels (y axis). Each point is one accession, colored by data source in Figure 1C. Cvi-0 and UKID116 are the most hypomethylated accessions, while Dör-10 is the most hypermethylated.
- (B) A snapshot of the 1001 Epigenomes Anno-J browser (<http://neomorph.salk.edu/1001.php>) for an example region on chromosome 1, showing hyper-, average, and hypo-gbM methylation in Dör-10, Col-0, and Cvi-0. Top track is gene model and yellow ticks in the bottom three tracks indicate CG methylation levels at each cytosine.
- (C) Geographical distribution of hyper- and hypo-gbM accessions.
- (D) Population-wide relation between epiallele and gene expression levels. Expression levels are shown as log<sub>2</sub>(FPKM + 1). UM, unmethylated genes; gbM, gene body methylated genes; teM, TE-like methylated genes.
- (E) Comparison of pairwise correlations for mCG within gene bodies (x axis) and mRNA abundance across all accessions (y axis), indicating positions for hypomethylated Cvi-0 versus hypermethylated Bak-5, Cvi-0 versus average methylated Col-0, and Col-0 versus Bak-5.
- (F) Transcript abundance (left) of hypermethylated (Bak-5), average (Col-0), and hypomethylated (Cvi-0, UKID116) accessions and mCG within gene bodies (right). Genes were sorted by average expression level.
- (G) AnnoJ browser snapshots for representative poly-epiallelic (PE) genes AT1G10190 and AT2G07680 that show gbM (mainly mCG) or teM (all contexts) in selected accessions.

(legend continued on next page)

might be linked to environmental adaptation by regulating responsive gene expression.

### Gene Body Methylation Does Not Have a Major Role in Shaping Transcriptome Variation

We examined gbM variation in our dataset, defined as CG-only methylation within gene bodies with a depletion of methylation at transcription start sites (TSS) and transcription termination sites (TTS). The numbers of genes with gbM were highly variable between accessions and positively correlated with the average mCG levels of these genes (Figures 2A and 2B; Pearson's  $r = 0.62$ ,  $p < 2e-16$ ). In relation to geographical origins, hypermethylated accessions were generally found in Sweden (Fisher exact test  $p = 4.0e-9$ ), whereas hypomethylated accessions were found mainly in Spain (Fisher exact test  $p = 1.4e-3$ ; Figure 2C).

gbM is associated with constitutive gene expression (Tran et al., 2005; Zhang et al., 2006; Zilberman et al., 2007), and the expression levels of gbM genes were indeed higher than those of unmethylated (UM) and TE-like methylated (teM; mCHG or mCHH and/or mCG) genes across all tested accessions (Figure 2D; Wilcoxon rank sum test  $p < 2.2e-16$  and  $p < 2.2e-16$ , respectively). To examine genome-wide relationship between gbM levels and transcription, we compared pairwise correlations for mCG within gene bodies and those for gene transcript levels (Figure 2E). Transcriptomes among accessions were more similar to each other than mCG levels (Wilcoxon rank sum test  $p < 2.2e-16$ ). Notably, although the hypomethylated accessions Cvi-0 and UKID116 exhibited greatly reduced gbM mCG levels, global gene expression levels were similar to the moderately methylated Col-0 and the hypermethylated Bak-5 (Figures 2E and 2F). These results suggest that although gbM is correlated with constitutive gene expression in the Col-0 reference, it is largely dispensable under laboratory growth conditions, which is consistent with recent observations of a complete loss of gbM in some angiosperms (Bewick et al., 2016). Indeed, it has been argued that gbM is either a direct or indirect consequence of transcription rather than a cause (Teixeira and Colot, 2009; Inagaki and Kakutani, 2012).

### Establishment and Reversal of TE-Like Methylation of Genes

Our DMR analyses revealed that certain genes were poly-epiallelic (PE) with some accessions being unmethylated and some exhibiting gbM and some teM. Examining the 846 accessions grown at Salk, we found 21,939 genes that had gbM in at least one accession, 8,889 genes that had teM in at least one accession, and 7,524 genes that were part of both sets (PE; Figures 2G

and 2H). In general, teM epialleles were less frequent than gbM epialleles (Figure 2I), which were typically shared by about 90% of the accessions, suggesting that the teM alleles are younger than the gbM alleles. Interestingly, teM of 2,053 PE genes (27%) was found in single accessions (teM singletons). So-called relict accessions (The 1001 Genomes Consortium, 2016), which occur at low frequency around the Mediterranean and are the product of ice age refugia, generally contained more teM singletons (Figure 2J; Wilcoxon rank sum test  $p = 2.1e-7$ ).

Next, we examined the functional relevance of gbM versus teM. Compared to non-PE genes, PE genes had more non-synonymous mutations (Figure 2K; Wilcoxon rank sum test  $p = 4.0e-236$ ), and were less likely to be duplicated (13% versus 18%; Fisher exact test  $p = 5.1e-31$ ) but were more often members of multi-gene families (54% versus 45%; Fisher exact test:  $p = 2.1e-36$ ). GO analysis of PE genes identified enrichment for phosphorylation-related and, similar to C-DMRs, immune-response-related terms (Figure 2L), suggesting that PE genes are generally involved in signaling and metabolic processes.

Among the 1,934 genes that have gbM and teM epialleles in at least five accessions, 199 teM genes have significantly lower expression (FDR < 0.05) than their gbM epialleles. Notably, the teM epialleles of the temperature-dependent flowering repressor *MADS AFFECTING FLOWERING 3* (*MAF3*; Ratcliffe et al., 2003) was associated with lower expression (Figure 2M). Although we did not detect a significant association between flowering time at 10°C or 16°C (The 1001 Genomes Consortium, 2016) and the epialleles (Wilcoxon rank sum test  $p > 0.01$ ), it is possible that teM associated reduction in *MAF3* expression is involved in flowering variation under natural conditions.

One possible explanation for the emergence of poly-epialleles is the spreading of RNA-directed DNA methylation (RdDM) from nearby TEs. Consistent with this, TE annotations were enriched within 500 bp or inside PE genes that were teM in Col-0, compared to all protein-coding genes (Fisher exact test  $p = 0.015$ ). The remaining 367 PE genes showed enrichment of mCHH in gene bodies (Figure 2N). Other known potential triggers of teM include inverted repeats and RdDM triggered by unlinked loci, but it is also possible that aberrant mRNAs or gene-silencing-associated RNAs are produced from gbM genes and processed into siRNAs (small interfering RNA), with the potential to promote non-canonical RdDM within these genes and their paralogs (Nuthikattu et al., 2013; Pecinka et al., 2013).

### Multiple Pathways Contribute to Methylation Variation

We next examined overall methylation levels across the 1001 Epigenomes population, focusing in particular on the correlation

(H) Venn diagram for the numbers of gbM genes, teM genes, and their overlap (PE genes), based on Salk-grown samples.

(I) Binning of PE genes based on gbM frequency (the fraction of accessions with gbM epiallele among Salk-grown accessions) and teM frequency. Each tile on the heatmap indicates the number of PE genes in the corresponding bin.

(J) Density distribution of teM singletons in relict and non-relict accessions.

(K) Enrichment of PE genes for major effect mutations.

(L) Enrichment of PE genes for GO terms related to immunity and phosphorylation.

(M) Association of epiallele state and gene expression level at *MAF3*.

(N) Heatmap of CHH methylation around PE genes that have a teM epiallele, but do not contain TEs within their gene bodies or within 500 bp up/downstream in Col-0. TSS, transcription start site; TTS, transcription termination site.

**Figure 3. Global Patterns of Methylation Variation**

(A) Average CHH methylation levels of CMT2 targeted TEs (x axis) and RdDM targeted TEs (y axis) in worldwide accessions and mutants.  
 (B) Geographic distribution of Salk-grown accessions with hypermethylated TEs and hypomethylated CMT2/RdDM targeted TEs.  
 (C) Heatmap for kinship-corrected correlations between the genome-wide methylation level for a particular methylation context (in columns) and environmental/geographic variables (in the rows). Rows and columns were ordered by clustering by similarity in correlation. Pre., precipitation; Temp., temperature.  
 (D) The fraction of variation in genome-wide methylation (all contexts) across accessions that can be explained by genome-wide kinship, i.e., SNP heritability. See also [Supplemental Experimental Procedures](#).

between methylation in different contexts and on the correlation with climate and geography. mCHH in TEs is separately catalyzed by two distinct DNA methyltransferases, DOMAINS REARRANGED METHYLTRANSFERASE 2 (DRM2) in the RdDM pathway and CHROMOMETHYLASE 2 (CMT2), which recognizes heterochromatic regions via H3K9 di-methylation (Stroud et al., 2014; Zemach et al., 2013). To distinguish these pathways, we considered TEs affected in *drm1* *drm2* and *cmt2* mutants, respectively (Stroud et al., 2013). Methylation was correlated between these two contexts, and comparison with data from plants grown at lower temperatures confirmed the positive correlation between temperature and mCHH (Figure 3A; Dubin et al., 2015). For leaf samples from Salk-grown accessions, hypermethylated accessions were mainly found in Germany (Fisher exact test  $p = 2.0e-7$ ), whereas hypomethylated accessions were almost randomly distributed (Figure 3B). In summary, mCHH variation within TEs is likely due to differences in a combination of pathways, guided by environmental and developmental cues.

The pattern of correlation, across individuals and between methylation and environmental variables (Figure 3C), revealed clear similarities between all types of mCHH, whether RdDM- or CMT2-targeted, and the same for mCHG. However, mCG behaved very differently in that mCG of TEs was correlated with mCHH, while mCG gbM was correlated with mCHG. This finding

strongly suggests that not all mCG is created equally. It also supports the notion that gbM is connected to CMT3 and mCHG (Miura et al., 2009; Bewick et al., 2016). mCG also stood out in terms of its genetic architecture (Figure 3D). Viewed as a phenotype, the variation of mCG across lines was well explained by genome-wide SNP variation. It is thus heritable in the statistical sense, which is entirely consistent with it being heritable in the direct sense of being stably transmitted across generations through meiosis.

All types of methylation showed striking correlations with place of origin and its climate (Figure 3C). Very broadly, methylation levels within TEs were positively correlated with latitude and precipitation and negatively correlated with warmer temperatures. The correlation between TE methylation and temperature of origin is thus the opposite of the correlation between TE methylation and experimental growth temperature (Figures 3A and 3C), suggesting that temperature compensation has evolved in the natural range (Shen et al., 2014; Dubin et al., 2015). gbM again behaved very differently and showed strong correlation with colder winters (Dubin et al., 2015).

#### Genome-Wide Association Reveals the Genetic Basis of Methylation Variation

To gain further insight into the genetics of methylation, we turned to genome-wide association studies (GWAS), using the

**Figure 4. Genome-Wide Association Study on Methylation Levels**

(A–C) Manhattan plots of GWAS results for genome-wide average methylation phenotypes. (A) CHH methylation of RdDM-targeted TEs. (B) CHH methylation of CMT2-targeted TEs. (C) CG gbM. Highlights indicate peaks containing strong *a priori* candidates. Horizontal gray solid and dashed lines indicate genome-wide threshold  $p = 0.05$  with Bonferroni correction and FDR 20% defined by enrichment analysis, respectively. Only SNP with minor allele frequency (MAF) >5% are included.

(D–F) Enrichment and FDR corresponding to (A–C) (based on enrichment of *a priori* candidates, see [Supplemental Experimental Procedures](#)). The horizontal dashed lines at 0.2 correspond to FDR 20%.

(G and H) Close up of chromosome 5 peak around *AGO9* corresponding to (A and B). Green dots show non-reference SNPs with MAF > 5%, and gray dots show rare SNPs (MAF 1%-5%).

See also [Figures S2](#) and [S3](#).

dense SNP data available for our sample with minor allele frequency (MAF) 5% cutoff. For TE methylation, several peaks with genome-wide significance were detected ([Figures 4A](#) and [4B](#)), and there was massive enrichment for *a priori* candidates ([Figures 4D](#) and [4E](#)). Among the latter, our analysis confirmed the previously reported strong effect of *CMT2* itself on CMT2-dependent mCHH ([Dubin et al., 2015](#)), but the top SNP here is considerably closer to the gene (chr4:10,422,486, 1.2 kb downstream of *CMT2*,  $-\log_{10} p = 7.88$ ). Another striking candidate was *ARGONAUTE 9* (*AGO9*), which is involved in siRNA silencing, and for which natural variants have been connected to differences in epigenetic control of cell specification ([Rodríguez-Leal et al., 2015](#)). Interestingly, *AGO9* appears to be associated both with RdDM- and CMT2-dependent mCHH, although the SNPs associated differ, suggesting that different alleles are involved. For RdDM-targeted mCHH, the top SNP

was >200 kb away from the coding region (chr5:7,344,821,  $-\log_{10} p = 6.78$ ), whereas for CMT2-dependent mCHH the top SNP was located 16 kb downstream of *AGO9* (chr5:7,214,350,  $-\log_{10} p = 6.13$ ). However, multiple rare alleles may be responsible for both associations, because if we include rarer SNPs in the analysis (see below), we find several highly significant associations very close to *AGO9* (top SNP 3.6 kb downstream; chr5:7,201,933,  $-\log_{10} p = 11.69$  in CMT2-targeted mCHH, 8.15 in RdDM-targeted mCHH, minor allele count = 21; [Figures 4G](#), [4H](#), [S2A](#), and [S2B](#)). The more distant top SNPs may thus be “synthetic” or “ghost” associations ([Atwell et al., 2010](#)).

GWAS for RdDM-dependent mCHH also identified another argonaute gene, *ARGONAUTE 1* (*AGO1*), with a crucial role in post-transcriptional gene silencing ([Brodersen et al., 2008](#); the top SNP is found in the promoter region: chr1:17,895,231,  $-\log_{10} p = 6.10$ ), and *NUCLEAR RNA POLYMERASE D1B*

(*NRPD1B*), which encodes the largest subunit of nuclear DNA-dependent RNA polymerase V, and is an essential component of the RdDM pathway (Law and Jacobsen, 2010; top SNP 0.5 kb downstream: chr2:16,724,013,  $-\log_{10} p = 6.74$ ).

There was striking enrichment of a priori candidates even for  $p$  value cutoffs well below genome-wide significance (Figures 4D and 4E), demonstrating that many non-significant associations deserve further investigation. Strong enrichment was also found when we allowed associations with rarer alleles (Figures 4G, 4H, S2A, and S2B) or used a slightly less conservative correction for population structure (Figures S2D and S2E), although both cases produced clearly biased  $p$  values (Figure S3). Among the notable candidates identified this way was *METHYL-CPG-BINDING DOMAIN 3* (*MBD3*), for which several non-synonymous polymorphisms are associated with CMT2-dependent mCHH (Figure S2B).

These less conservative approaches also identify a clear candidate for gBM, which otherwise has no clear associations (Figures 4C and 4F). Although significance levels are clearly inflated (Figure S3), we find a strong association at *DNA METHYLTRANSFERASE 1* (*MET1*), which is responsible for replication of CG methylation (Kawashima and Berger 2014) and, hence, is an excellent candidate (Figure S2F, chr5: 19,925,444,  $-\log_{10} p = 9.02$ ).

### Natural Variations of Transcriptomes and Transcriptional Regulation

Because DNA methylation can modulate gene expression, we next analyzed the transcriptomes from 727 accessions grown at 22°C (Figure 1C). These accessions express, on average, transcripts from 18,000 genes (Figure 5A). Comparing groups of accessions defined by genetic distances (The 1001 Genomes Consortium, 2016), we found 5,725 differentially expressed genes (DEGs) between relict accessions, an ancestral diverse group, and non-relict accessions (Figure 5B). These DEGs were a subset of the 22,085 DEGs between all admixture groups (Figure 5B; Table S4), suggesting further diversification of the transcriptomes among geographic groups. The two sets of DEGs were enriched for distinct biological processes (Figure 5C). The most variable genes were enriched in functions related to biotic and temperature responses, likely reflecting adaptation to their natural environments. DEGs between relict and non-relict groups were enriched in ribosomal biogenesis and translation processes, suggesting the regulation of this energy-intensive process contributed to the successful expansion of non-relict groups.

Co-expression network analysis (Langfelder and Horvath, 2008) identified eight modules each for relict and non-relict accessions (Table S4). Seven of the eight relict modules had significant overlap with at least one non-relict module (Figure 5D) and were enriched for distinct biological processes preserved in one of the overlapping non-relict modules (Figure 5E): biotic responses (M4 and M5; Figure 5F), abiotic responses (M1; Figure 5G), development (M2; Figure 5H), cell cycle (M3; Figure S4A), and photosynthesis (M7 and M8; Figure S4B). The non-relict modules showed no or weak correlation with flowering time (Atwell et al., 2010; Figure S4C), suggesting that coexpression is unlikely driven by developmental stage at the time of sam-

ple collection. Using transcription factor binding sites (TFBS) identified by DNA affinity purification sequencing (DAP-seq) for the non-relict accession Col-0 (O’Malley et al., 2016), we found that non-relict modules were targeted by distinct TF families (Figures 5I and S4D), including the expected WRKY TFs for the biotic response modules, bZIPs for abiotic response modules, NACs for the development module, as well as yet unknown connections. Further DAP-seq experiments using TF variants and DNA from relict accessions will provide evidence for the mechanism behind preservation and emergence of co-expression modules (Figure 5E).

To link methylation and expression differences, we mapped expression quantitative trait loci (eQTL) with the 1001 Genomes SNP data, which identified genetic loci associated with gene expression. We then used GWA of gene expression with differentially methylated bins (100 bp; DMB) to pinpoint methylation-dependent eQTL (eQTL<sup>epi</sup>, in which *epi* is CG-, CH-, C-DMB; Table S5). Both cis-eQTL and cis-eQTL<sup>epi</sup> were enriched at the TSS, and the highest numbers of cis-eQTL<sup>epi</sup> were found for CH- and C-DMB (Figure 6A), consistent with the silencing effect of these methylation contexts. As TF binding provides a mechanism for how methylation may affect gene expression, we compared the genetic and methylation variants to the 2.7 million TFBS of 329 TFs identified on Col-0 leaf DNA with methylcytosines (Col-0 cistrome) and the additional ~180,000 TFBS identified on methylation-free DNA (Col-0 epicistrome; O’Malley et al., 2016). ~25% of CH-DMBs (73,366) and 22% (48,109) of C-DMBs overlapped with the Col-0 cistrome and epicistrome (Figures 6B and 6C), regions that harbor binding sites that may become available or occluded depending on the methylation state. Merged binding profiles of TF families showed two patterns of enrichment in DMBs (Figure S5A). Of 45 families, 13 were depleted in CG-DMB but slightly enriched in CH-DMB, and one, the E2FDP family, was specifically enriched in C-DMB. This family includes the cell-cycle regulator E2F, and methylation-regulated transcription is a potential mechanism for cell-cycle variations (Sterken et al., 2009).

Members of the same TF family that have similar binding motifs may differ in their genome-wide binding profiles (O’Malley et al., 2016). We therefore also performed enrichment analysis on individual TFs. Most TF-binding sites were depleted at eQTL<sup>CH-DMB</sup> while the associations with eQTL were evenly distributed between enrichment and depletion (Figure 6D). Ranking of the TFs by enrichment in eQTL or eQTL<sup>CH-DMB</sup> identified three groups (Figure 6D, solid and dashed lines, and Figure 6E). Group 1, including the C2H2 zinc-finger TF STZ, had binding sites enriched in both eQTL and eQTL<sup>CH-DMB</sup>. Binding sites for group 2 and 3 were enriched in either eQTL or eQTL<sup>CH-DMB</sup>, respectively. Group 2 TF included the heat shock response factor HSFA6B and the meristem formation TF CUC2. MYB-related family members were found in both Group 1 (AT1G74840) and Group 3 (EPR1, AT4G01280, AT3G10113). These results suggest that genome and methylome variation interact to regulate gene expression through distinct sets of TFs.

In mammals, methylation in both CG and non-CG contexts is absent in binding sites of selected TFs (Lister et al., 2009; Domcke et al., 2015), but the relationship between methylation variation in natural populations and TF binding has not been

### Epigenome Variation Is Shaped by Genome Structural Variation

Our methylome analyses were based on the Col-0 reference genome substituted with accession-specific SNPs and small deletions, but did not include structural variation (SV) information, which may also affect plant epigenomes (Lisch, 2013). To relate SVs to methylome variation, we created physical genome maps (contigs) for nine accessions that represent a high-diversity panel (The 1001 Genomes Consortium, 2016) including Col-0 as reference control (TAIR10; Figure 7A). These contigs were built from images of ultra-long fluorescently labeled DNA molecules (Lam et al., 2012). These averaged 284 kb (max. 1.5 Mb), long enough to span very large repeat arrays. The nine genomes assembled into 86 (Lesno-4) to 239 (Cvi-0) contigs (N50 > 1.1 Mb; Figure 7A).

Aligning the Col-0 contigs to the TAIR10 assembly identified 29 mis-assemblies in the original reference (2.5–59 kb, Table S6A). For the accessions in the diversity panel, alignments covered 76% (Cvi-0) to 94% (Lu4-2) of the reference (Figures 7A, 7C, and S6A), with most alignment gaps being pericentromeric (Tables S6A and S6B). We found an average of 6.2 SVs per Mb (Figure 7A), representing insertions, deletions (indels), or rearrangements relative to the reference. The German accessions Erg2-6 and Lu4-2 represented the lower (5.7 indels/Mb) and upper (6.8 indels) end of the range, although their collection sites were only 20 km apart. Indel size ranged between 2.5 kb (resolution cutoff) and >110 kb (average 10.8 kb; Figure 7B; Table S6A). Notably, each accession had on average 3.43 Mb unique sequences not present in the reference and lacked 3.54 Mb of reference sequences. The nearly symmetrical “gains” and “losses” relative to the reference set the optical maps apart from previous efforts based on de novo assemblies of short reads, which suffered from reference bias and therefore always reported more “losses” than “gains” (e.g., Cao et al., 2011). Since the reference largely lacks centromere sequences, these

analyzed systematically. Binding inhibition by methylation (O’Malley et al., 2016) was predicted to be stronger for TFs depleted at eQTL<sup>CH-DMB</sup> compared to those that are enriched for such loci (Figures 6D and 6E). This general trend held true for the entire set of 352 TFs with methylation inhibition data, i.e., the more strongly a TF was inhibited by mCH methylation, the more depleted its binding sites were at eQTL<sup>CH-DMB</sup>, while the level of methylation inhibition and enrichment at eQTL were not correlated (Figure 6F). The depletion of TFBS in mCH regions may be due to the low CG content of the TF motifs (Figure S5B), although the motif CG content also contributed to the methylation inhibition of binding (Figure S5C). This suggests a complex interplay between evolution of genetic and methylation variation and TF binding: binding sites for methylation inhibited TFs are selected against in methylated regions, possibly by the elimination of CG dinucleotides, to avoid dramatic changes in binding in response to methylation changes. Consistent with this hypothesis, TFs for which binding is enriched in eQTL<sup>CH-DMB</sup> have moderate methylation sensitivity (Group 3, Figures 6D and 6E), potentially allowing methylation changes to fine tune binding.

**Figure 7. Genome Structure Is Linked to Differential Methylation and Transcription**

(A) Summary of genome maps created using images of nick-labeled ultra-long DNA molecules for nine *Arabidopsis* accessions, including the reference accession Col-0. Columns are (from left): Accession ID, country of origin, total alignment length of optical maps against TAIR10 in Mb and percentage, counts for combined insertions and deletions (indels) per Mb of TAIR10, insertions per Mb, deletions per Mb, genes and TEs within indels, and insertions with hyper-, hypo-, or mixed DMRs.

(B) Boxplot for the length distribution of insertions (red) and deletions (blue) for all eight accessions in kb.

(C) Graphical representation of optical contigs aligned to chromosome 1 (green-boxed arrows). Black boxes show TAIR10 mis-assemblies. Arrows in magenta represent regions not present in TAIR10 (insertion), and blue represents regions absent in that accession (deletion).

(D) Overview of Yeg-8 chromosome 4 optical contig alignments (blue) against TAIR10 (gray). Crossing green and red lines identify two inversions. Red and yellow lines depict insertions and deletions against TAIR10. The dashed line represents 1.2 Mb of rDNA/nucleolar organizer. Labels show size in Mb.

(E) Alignments were used to call insertions (red) and deletions (blue) relative to the TAIR10 reference. A large portion of SVs is shared among accessions.

(F) *RRS1-RPS4* NLR locus on chromosome 5, comparing Erg2-6 and IP-Cum-1 to Col-0. TAIR10 annotations are shown on top as non-NLR genes (gray), NLR genes (black), TEs (orange), and F-box gene (green; see 7G). Both methylated cytosines (mC) and WGS read coverage (read) tracks are shown per accession. Grey bars show mapping-free regions that overlap with predicted SV loci (dashed lines), and size differences are indicated.

(G) Transcript expression levels of three genes in accessions in which the gene overlap with deletion (Del), reference (Ref), and insertion (In) loci. The y axis shows normalized RNA-seq read counts.

See also Figure S6 and Table S6 and S7.

statistics only reflect variation in the chromosome arms. The “deletion” or “absence” alleles were more likely to be the major alleles than “insertion” or “presence” alleles, which were also less frequently shared between accessions (46%) than deletion alleles (67%; **Figure 7E**). In fact, only 5% of all insertions, but 22% of all deletions were shared among six or more accessions. This is expected if *A. thaliana* genomes are continuing to shrink, as suggested before (Hu et al., 2011). Indels were dispersed along the chromosomes with increasing density of shared insertions toward the centromeres (**Figures 7C** and **S6A**). Physical contigs also allowed us to observe large-scale rearrangements and more complex SVs, such as a 1.2 Mb inversion on the short arm of chromosome 4 (Fransz et al., 2000), and a local translocation on chromosome 1 where DNA fragments (289 kb Cvi-0 and 412 kb Lesno-4) swapped place with a neighboring fragment, without changing orientation. As another example, Yeg-8 chromosome 4 (**Figure 7D**) harbored a local inverted translocation of 907 kb, including a 323 kb insertion.

As the physical contigs do not provide DNA sequence content, we analyzed reference annotations around the SVs. TEs were present in the vast majority of SV loci (92%; **Table S6C**). Helitron-class TEs were enriched around insertions, potentially reflecting copy-number variation as Helitrons replicate as rolling circles (Kapitonov and Jurka, 2001). Genes, present in 86% of SVs, were functionally enriched for defense response with emphasis on NLR genes, independent of SV-type (in/del, shared/unique; **Table S6D**). Indeed, NLRs reside in highly syntenic and TE-rich clusters (Meyers et al., 2003; Leister, 2004), and 37% of TEs within 10 kb of NLR genes inside SVs were Helitrons.

The nine accessions analyzed had together 1,317 PE genes, with 729 (55%) being in SV regions (**Table S6E**; Fisher exact test  $p = 4.3e-58$ ). Insertion or deletion of TEs in combination with rapid silencing of recently inserted TEs may change the propensity of genes to change epiallelic state. We speculate that a subset, if not all, of the remaining 588 PE genes were located in SVs smaller than 2.5 kb and thus undetected by our optical maps.

DMRs could only be analyzed at the borders of SVs, possibly reflecting gain or loss of spreading teM. In insertions, we observed hypermethylated DMRs in up to 11% and hypomethylated DMRs in up to 17% (**Table S6F**). Over half of all deletion sites were hypomethylated, and up to 17% harbored hypermethylated DMRs (**Table S6F**). Up to eight SVs per accession harbored both types of DMRs. Overall, 22%–50% of SVs were differentially methylated (**Table S6F**), suggesting SVs in natural populations are closely related to methylation variants.

### Disease Resistance Loci Are Major Targets of Both Structural and Methylation Variation

The predominant gene family linked to C-DMRs and PE loci were NLR-type disease resistance genes (**Figures 2L** and **S1N**), which represent one of the largest plant gene families with over 150 members in *A. thaliana*. Our physical contigs were particularly variable at NLR loci, consistent with previous, more limited analyses of individual NLR clusters (Chae et al., 2014; Leister, 2004; Meyers et al., 2003). To provide an example of such an extremely polymorphic region, we focused on a cluster of nine NLR genes in the reference Col-0, which includes the NLR pair *RRS1/RPS4*

(chr5:18,150,000-18,352,500; Gassmann et al., 1999). Indels, on average five (**Table S7**), expanded this region (Col-0 201 kb) by up to 9 kb (Yeg-8) or shrunk it by up to 11 kb relative to the reference (IP-Cum-1; **Figure S6B**). *RRS1B* and *RPS4B* (Saucet et al., 2015) were present in all accessions, flanked by 12 differentially methylated TEs (Helitron and MuDR; **Figures 7F** and **S6B**). While transcriptome data revealed no effect of the variable proximal indel state, a close-by F-box gene (*AT5G44980*) had elevated expression levels in accessions with overlapping insertions, suggesting a duplication and dosage effect (**Figure 7G**). The larger *RRS1/RPS4* sub-cluster encodes 7 NLRs and 29 differentially methylated TEs (Col-0), seven within NLR introns (*AT5G45200*, 2 Helitron; *AT5G45230*, 4 MuDR; *RRS1*, 1 MuDR) but without effects on expression levels. The *RRS1/RPS4* pair was, in contrast to *RRS1B/RPS4B*, only expressed in indel-free lines (**Figure 7G**; **Table S7**).

Importantly, while the lack of mapped short reads from genome and methylome sequencing had suggested deletions of three NLRs (*AT5G45220*, *AT5G45230*, and *AT5G45240*) in three accessions (21 kb; Lu4-2, Nicas-1 and Yeg-8), and additionally of *RRS1/RPS4* (36 kb total) in IP-Cum-1 (**Figure S6B**), optical map contigs provided clear evidence for insertions rather than deletions, indicating that these regions can be completely replaced by unknown sequence content.

### Conclusions

The *A. thaliana* 1001 Epigenomes project provides evidence that methylation is correlated with geography and climate of origin. This supports the notion that methylation plays a role in adaptation (**Figure 3C**; Dubin et al., 2015). Indeed, our study shows that epigenomic changes are associated with environmental responses, and especially immunity genes. This makes plants distinct from humans, in which epigenomic changes in germ cells (Gkountela et al., 2015; Guo et al., 2015; Tang et al., 2015) or adult tissues (Schultz et al., 2015) are associated with developmental control genes.

TEs are responsible for most indels and are enriched at disease resistance loci, in which Helitron and MuDR transposons shape gene arrangements, DNA methylation, and gene expression. While we identify that gbM is not required for a functional transcriptome, epiallele conversion between gbM and teM, likely induced by TE movement, can be a part of the evolutionary toolbox to alter gene expression either directly on the gene, or its regulatory elements. Selection could also explain the existence of major alleles leading to striking GWAS results for TE methylation. Further exploration of these should provide insight into the evolution and function of this genomic immune system.

TF binding may provide a further mechanism for linking genome and epigenome variation to adaptation: binding sites for distinct sets of TFs may respond to changes in sequence and methylation to establish gene expression modules for major biological processes essential for adaptation.

Surprisingly, AGO1 and AGO9 were associated with genome-wide average mCHH levels, given that knockout of either locus does not affect average mCHH levels within RdDM-target regions (Stroud et al., 2013). Importantly, GWAS associations not only identified genes known to be involved in epigenetics, but also novel loci. Identifying these genes (which could be lethal

when knocked out) would lead to significant insight into DNA methylation and gene-silencing pathways.

Methylome studies for crops like rice, maize, and soybean, which have larger genomes with expanded TE families, have higher mCG and mCHG levels but similar mCHH levels compared to *Arabidopsis* (Niederhuth et al., 2016; Seymour et al., 2014; Takuno et al., 2016). Since TE transposition greatly impacts epigenomic diversity among *A. thaliana* accessions, crops are likely to show much more local epigenomic diversity within a species. The high variability in average methylation levels between *A. thaliana* accessions is a reminder that conclusions about species-specific DNA methylomes based on single accessions should be met with caution. Deeper understanding of epigenome evolution is thus a prerequisite for future inter- and intraspecific comparative epigenomic studies.

SV analyses not only revealed that sequence gains and losses in individual accessions are nearly symmetrical, but also suggested a tight interplay between genome and epigenome evolution. The next step will be to integrate these with high-quality sequence-based genome assemblies as a prerequisite for identifying the specific DNA sequences that vary between accessions and that contribute to methylome and transcriptome variation.

## EXPERIMENTAL PROCEDURES

Please see [Supplemental Experimental Procedures](#) for detailed experimental and analysis methods.

### Plant Materials

Seeds are available from the *Arabidopsis* Biological Resource Center (ABRC) under accession IDs CS76427, CS76636, CS78885, and CS78942.

### MethylC-Seq

MethylC-seq library preparation, read mapping, and base calling was performed as described previously (Lister et al., 2011).

### Identification of Differentially Methylated Regions

Differentially methylated regions (DMRs) were identified using the methylpy pipeline (Schultz et al., 2015). Methylation levels of each region are calculated as the frequency of C base calls at C positions within the region divided by the frequency of C and T base calls at C positions within the region.

### RNA-Seq and Identification of Differentially Expressed Genes

RNA-seq libraries were prepared using Truseq RNA kit (Illumina, San Diego) following manufacturer's instruction. Reads were mapped using STAR aligner (Dobin et al., 2013) to TAIR10 genome and annotation. Gene level expression was quantified for TAIR10 annotated genes and batch normalized by the RUVseq package (Risso et al., 2014). Differentially expressed genes were called by the DESeq2 package (Love et al., 2014).

### Physical Mapping and Identification of Structural Variations

HMW DNA was extracted using the Fix'n'Chop protocol (BioNano Genomics, San Diego) and then fluorescently nick-labeled (Nt.BspQI; New England Biolabs, Ipswich) using IrysPrep kit. Single molecule physical mapping was performed using the BioNano Genomics Irys system following manufacturer's recommendations. Molecule data were assembled using IrysView 2.3 and SVs were called using custom Python scripts.

### Genome-Wide Association Studies

Genome-wide association mapping was performed using EMMA algorithm (Kang et al., 2010). eQTL and eQTL<sup>epi</sup> analysis was performed by the LIMIX (Lippert et al., 2014).

## Data Release

Data can be visualized using the 1001 Epigenomes Project genome browser (<http://neomorph.salk.edu/1001.php>).

## ACCESSION NUMBERS

The accession number for the MethylC-seq data reported in this paper is GEO: GSE43857. The accession number for the RNA-seq data reported in this paper is GEO: GSE80744. Optical genome maps are available at <http://signal.salk.edu/opticalmaps/>.

## SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures, seven figures, and seven tables and can be found with this article online at <http://dx.doi.org/10.1016/j.cell.2016.06.044>.
