25

26 **Abstract**

27 Natural systems are predicted to be exposed to more frequent and more intense drought events
28 in the near future. Plant-plant interactions form an important part of the whole of mechanisms
29 that govern the responses of plant species and communities to drought. The accuracy of
30 predictions on ecosystem functioning would therefore be improved by determining when
31 plant interactions need to be considered and how these interactions can drive species
32 responses. In this study, we assessed the effect of neighbour plants on the drought response of
33 a target plant. Two grassland species (*Plantago lanceolata* and *Lolium perenne*) were grown
34 in the presence of either six conspecific or three conspecific and three heterospecific
35 neighbours in sunlit growth chambers. They were subjected to drought by withholding water
36 for 20 days. Regardless of the identity of the target plant, having *P. lanceolata* as a neighbour
37 increased the susceptibility to negative drought effects on biomass production while *L.*
38 *perenne* neighbours buffered the target's drought response. Our results therefore suggest that
39 drought responses depended largely on the identity and the traits of the neighbours. Such
40 findings demonstrate that current models to predict ecosystem functioning may be misleading
41 by not sufficiently taking plant-plant interactions into account.

46

47 **Introduction**

48 Natural systems are increasingly subjected to environmental change. Low soil water
49 availability caused by drought is one of the major limitations for plant growth (Chaves and
50 Oliveira, 2004; Schulze et al., 1987), while the probability and severity of drought episodes is
51 projected to further increase (IPCC, 2013). Drought studies have therefore been carried out in
52 considerable numbers, typically focusing on the morphological, physiological and
53 biochemical changes of individual plants (e.g. Chaves et al., 2002; Flexas et al., 2004; Lawlor
54 and Tezara, 2009). Decreased water availability limits plant productivity mainly by stomatal
55 closure, down-regulation of photosynthesis, slower cell expansion and/or by carbon allocation
56 to the roots and to protective molecules (Benjamin and Nielsen, 2006; Chaves et al., 2002;
57 Praba et al., 2009). However, how individual plants in a community respond to water
58 deprivation is not only determined by species-specific characteristics but also by the nature of
59 interactions with neighbouring plants.

60 Differences between species in the ability to sequester resources and to produce biomass lead
61 to diverse plant-plant interactions involving competition and partitioning of resources in
62 varying degrees (Hooper, 1998; Hooper et al., 2005; Verheyen et al., 2008). These
63 interactions are obviously critical in determining the outcome of the response to resource
64 depletion. For instance, if competition between species for water is low, a species will likely
65 respond less to water deprivation when surrounded by neighbours from the other species (=
66 heterospecific) than when surrounded by neighbours from the same species (= conspecific) (if
67 the water content before the onset the drought is similar, see Van Peer et al. 2004). Spatial
68 complementarity in water use occurs when species differ in root distribution, so that
69 heterospecific neighbours at least partially extract water from different soil zones (Nippert
70 and Knapp, 2007; Verheyen et al., 2008). On the other hand, differences in water use between
71 species can cause an altered timing and intensity of soil drying, which can favour or

72 disadvantage the target's susceptibility to water deprivation. If a species is surrounded by
73 neighbours with a high water consumption, it will likely suffer from water deprivation earlier
74 than if it were surrounded by water saving species, irrespective of whether its neighbours are
75 con- or heterospecific.

76 In this study, two target species were subjected to drought by withholding water for 20 days.
77 To investigate the importance of neighbours on the drought response, the targets were
78 surrounded either by six conspecific or by an equal mix of conspecific and heterospecific
79 neighbours. We hypothesize that, if complementarity is limited, such as is presumably the
80 case for the two species we selected (Weeve 1975), neighbours can favour or disadvantage
81 target plants, by altering the water availability for the targets, depending on the rate of water
82 use of the neighbours. To detect these effects, we determined above- and below-ground
83 biomass, soil water status, stomatal conductance and photosynthesis.

84

85 **Materials and Methods**

86 Experimental set-up

87 For this study, two common and co-occurring grassland species with comparable height and
88 rooting depth (Weeve, 1975) (*Lolium perenne* L. and *Plantago lanceolata* L.) were each
89 grown as target plant surrounded by six neighbour plants at equal distances. The six
90 neighbours were either conspecific to the target (further referred to as 'conspecific
91 neighbours') or composed of three conspecific and three heterospecific plants (further referred
92 to as 'heterospecific neighbours') (Fig. 1). This yields four designs with different
93 combinations of targets and neighbours: *L. perenne* or *P. lanceolata* with conspecific or
94 heterospecific neighbours (further referred to as L_{con} , L_{het} , P_{con} and P_{het} , respectively) (Fig. 1).
95 The species were sown end of March 2010, with a time lag to prevent differences in size at
96 the start of the experiment (Cotrufo and Gorissen, 1997) due to differences in germination rate

97 (*P. lanceolata* day of year (DOY) 76, *L. perenne* DOY 88). The seedlings were transplanted
98 end of April (DOY 116 - 118) in PVC containers (19 cm inner diameter, 40 cm height, 11.33
99 L), filled with sandy soil (93.2% sand, 4.6% silt, 2.2% clay; field capacity 0.13 m³ m⁻³; pH
100 7.6; total Kjeldahl-N 0.42 g kg⁻¹; 1% C in humus). The seven plants were placed in a
101 hexagonal grid at 5 cm interspace with the target species positioned at the centre of the grid.
102 All communities were fertilised with 10 g m⁻² NH₄NO₃, 5 g m⁻² P₂O₅, 10 g m⁻² K₂O and
103 micro-elements (Fe, Mn, Zn, Cu, B, Mo). The fertiliser was given dissolved in water in two
104 equal amounts at DOY 140 and 180.

105 Three replicates per design (yielding 12 containers) were randomly placed in each of eight
106 sunlit, climate-controlled chambers facing south. The study was conducted in climate
107 controlled greenhouses so that water deprivation was the only environmental variable. The
108 chambers followed fluctuating air temperatures mimicking an average daily air temperature
109 course, calculated over the period 1996 - 2005. The distances between the chambers were
110 maximised to avoid mutual shading. The interior surface area was 1.5 x 1.5 m, the height at
111 the north side 1.5 m and at the south side 1.2 m. The top of the chambers consisted of a
112 colourless polycarbonate plate (4 mm thick), whereas the sides were made of polyethylene
113 film (200 µm thick), both UV transparent. The experimental set-up is located at the Drie
114 Eiken Campus, University of Antwerp, Wilrijk, Belgium (51° 09' N, 04° 24' E), where
115 average annual precipitation is 776 mm (evenly distributed throughout the year) and average
116 annual air temperature 10.6 °C. Every half hour, the air temperature was monitored with a
117 temperature sensor (Siemens, type QFA66, Erlangen, Germany). During the experiment (28
118 April – 5 August 2010, DOY 118 - 217), monthly average air temperature was 12.7, 18.4 and
119 20.9 °C in May, June and July, respectively.

120 Irrigation was calculated from the monthly rainfall over the period 1995-2005 and corrected
121 for differences in evapotranspiration (ET) inside and outside the chambers. To this end, De

122 Boeck et al. (2006) calculated ET inside the chambers from changes in soil water content
123 (SWC) and the amount of administered water, and the outside ET with Hamon's equation
124 (Haith and Shoemaker, 1987) based on day length, vapour pressure and air temperature. The
125 containers were watered every two days according to the 10 year average of 14 to 15 raining
126 days per month during the growing season. Total monthly irrigation matched 61.5, 64.4 and
127 85.1 mm in May, June and July, respectively. Water could freely drain from the containers
128 while capillary rise of ground water towards the containers was prevented by a drainage
129 system placed below the chambers.

130

131 Imposed drought

132 Each design was subjected to two treatments: a drought treatment and a control treatment
133 (Fig. 1). The treatments were given at chamber level. Four of the eight chambers were
134 subjected to a period of water deprivation by withholding water for 20 days (DOY 197 - 217)
135 (referred to as 'imposed drought' or 'drought'). In the other four chambers, the watering
136 regime was not interrupted (control treatment). The length of the imposed drought was chosen
137 to be severe but not extreme, based on a previous experiment in the same climate chambers
138 and on the same soil, in which mesocosm communities were exposed to differing lengths of
139 imposed drought periods (Naudts et al., 2011). In each chamber, one container per design
140 contained a profile probe tube for the PR2 soil moisture sensor (Delta-T Devices Ltd., UK).
141 The probe was placed next to the centre of the container. Soil water content (SWC) was
142 measured once a week before the imposed drought (DOY 130 - 193) and twice a week during
143 drought (Table 1). For each container SWC was measured at three different depths (0, 20 and
144 40 cm) from which the mean was calculated.

145

146 Biomass harvest

147 The total leaf area of the communities (targets + neighbours) was determined with a portable
148 area meter (LI-3000A, Li-COR, NE, USA) just before the imposed drought (DOY 197) in one
149 replicate per chamber (drought treated and control communities were still identical at this
150 moment). Above-ground biomass of the targets was harvested immediately after the imposed
151 drought (DOY 217) in the two remaining replicates per design per chamber, in control
152 chambers as well as in drought treated chambers. Root biomass of the communities was
153 determined in one of these replicates. Root samples were washed until they were free of soil.
154 All plant material was dried at 70 °C for 48 h and then weighed. See Table 1 for details on
155 replicates and statistical analysis.

156

157 Gas exchange

158 All gas exchange measurements were conducted between 9 and 10 am on clear days to assure
159 comparable light conditions. Leaf stomatal conductance (g_s) of the targets was measured five
160 times during the imposed drought (DOY 197, 207, 210, 214 and 217), on the most recently
161 matured leaf with a porometer (AP4, Delta-T Devices Ltd., UK), taking into account abaxial
162 and adaxial sides of the leaves. Measurements were performed at the environmental
163 conditions in the chambers which is most relevant to detect the drought impact on stomatal
164 conductance. Before the start of the imposed drought (DOY 197) the pre-drought levels were
165 measured on one replicate per design in each of the eight chambers. During and at the end of
166 the drought two replicates per design were measured in each of the four chambers per
167 treatment, yielding eight measurements per design and treatment combination (see Table 1).
168 Light-saturated net CO₂ assimilation rate (A_{sat}) of the targets was determined on the most
169 recently matured leaf with a portable gas exchange system (LI-6400, Li-COR, NE, USA) at
170 the end of the imposed drought (DOY 217), in each of the four chambers per treatment (Table

171 1). Leaf chamber conditions were controlled at 380 ppm CO₂ and 23.5 °C (block temperature)
172 at saturating photon flux density (1500 μmol m⁻² s⁻¹) and ambient relative humidity.

173

174 Data analysis

175 The experiment had a split-split plot design with ‘treatment’ (control vs. drought) as the main
176 plot factor, ‘target species’ (*L. perenne* vs. *P. lanceolata*) as the subplot factor and
177 ‘neighbours’ (conspecific vs. heterospecific) as the sub-subplot factor (Fig. 1). Measurements
178 were conducted on the targets or on the whole community. They were conducted once or
179 repeated over time. All measurements were analysed with analyses of variance (ANOVA)
180 (see Table 1 for an overview). Chamber was always included in the model as a random factor
181 nested within treatment to test for possible chamber effects. The factor chamber was never
182 significant so was always excluded from the model. Non-significant interaction terms were
183 excluded from the model, while in case of significant interactions, the means were compared
184 a posteriori with Tukey corrections for multiple comparisons (see Table 2 and 3). Analyses
185 were performed in SAS (version 9.1, SAS Institute Inc., Cary, NC) using the mixed procedure
186 (Littell et al., 1996).

187 Above-ground biomass and A_{sat} of the targets were analysed separately for each target species
188 with treatment and neighbours as fixed factors. The course of g_s was measured only in the
189 drought treated targets and was analysed separately for each target species by repeated
190 measures (RM) ANOVA with DOY and neighbours as fixed factors. Additionally, g_s just
191 before the drought period (DOY 197), was compared between the two target species with
192 target species and neighbours as fixed factors and (Fig. 1).

193 Root biomass was measured at community level and analysed separately per target species
194 with treatment and neighbours as fixed factors. To compare total leaf area before the imposed
195 drought between all four designs the ANOVA was performed over both species, with design

196 as fixed factor. Mean SWC before and during drought was analysed with RM-ANOVA with
197 design and DOY as fixed factors. For the analysis of SWC during drought over the three
198 different depths, the fixed factor depth was added to the model.

199

200 **Results**

201 Biomass

202 The effect of an imposed drought on the above-ground biomass production of the target
203 species differed whether the targets were grown with conspecific or with heterospecific
204 neighbours. Moreover, the effect of neighbour type was opposite for the two target species
205 (Fig. 2). *Lolium perenne* targets grew as well under drought as under control conditions when
206 surrounded by conspecific neighbours, while biomass production was reduced by the imposed
207 drought when surrounded by heterospecifics (treatment \times neighbour significant, Table 2). For
208 *P. lanceolata* it was the other way around: the targets grew as well under drought as under
209 control conditions when surrounded by heterospecific neighbours, while biomass production
210 was reduced by an imposed drought when surrounded by conspecifics (treatment \times neighbour
211 significant, Table 2). Hence in both cases having *P. lanceolata* as a neighbour, either
212 conspecific or heterospecific, resulted in a more negative response to drought. The impact of
213 water deprivation on root biomass did not differ between the designs for *L. perenne* nor for *P.*
214 *lanceolata* (no treatment \times neighbour interaction, Table 2). Root biomass decreased with
215 drought for *P. lanceolata* (from 15.72 ± 0.88 (SE) to 11.99 ± 0.88 g m⁻²) while it did not
216 decrease for *L. perenne* (15.41 ± 1.10 and 12.88 ± 1.10 g m⁻² in drought and control
217 treatment, respectively).

218

219 Soil water status

220 Before the imposed drought, SWC was on average $0.12 \pm 0.01 \text{ m}^3 \text{ m}^{-3}$ (which is close to field
221 capacity) and no significant differences were observed between the different designs (P_{con} ,
222 L_{con} or heterospecific) (Table 3). From the onset of drought, SWC (mean over three different
223 depths) decreased in the drought treatments, with the decrease being faster in P_{con} than in L_{con}
224 or the heterospecific designs (significant $\text{DOY} \times \text{design}$ interaction, Table 3; a posteriori
225 comparison, Fig. 3). As a result, SWC in P_{con} designs reached its lowest point (wilting point)
226 earlier than in the other designs. In addition, SWC was lower in P_{con} designs than in the
227 heterospecific designs during half of the drought period (DOY 203, 208 and 211) and lower
228 than L_{con} on DOY 208 and 211. These results demonstrate that containers with only *P.*
229 *lanceolata* consumed more water than containers with *L. perenne* or with both species. The
230 same conclusion is drawn when analysing SWC at the different depths. Although all designs
231 dried faster at the surface than in the deeper layers, the faster decline of SWC in P_{con} designs
232 applied at each of the three depths (significant $\text{DOY} \times \text{design} \times \text{depth}$ interaction, Table 3; a
233 posteriori comparison, Fig. S1 and Table S1). Furthermore, SWC of P_{con} being lower than the
234 heterospecific designs during half of the drought period applied to depth = 0 and 20 cm and
235 for depth =40 cm SWC was lower only on DOY 208 and 211; this because the soil dries
236 slower at the bottom of the containers.

237

238 Gas exchange: g_s and A_{sat}

239 At the start of the imposed drought (DOY 197), g_s was significantly higher in *P. lanceolata*
240 than in *L. perenne*, irrespective of neighbour type (Table 3, Fig. 4). To be able to compare the
241 potential water consumption among the different designs at the start of the imposed drought,
242 both g_s and total leaf area need to be considered. Total leaf area at the start of drought did not
243 differ between the designs ($0.15 \pm 0.01 \text{ m}^2$ (SE), Table 3). Since *P. lanceolata* had the highest
244 g_s , water consumption was expected to increase with an increasing abundance of *P.*

245 *lanceolata*. Given that P_{con} systems contained the most individuals of *P. lanceolata*, these
246 communities were expected to consume the most water while L_{con} systems contained no *P.*
247 *lanceolata* individuals and therefore were expected to consume the least amounts of water.
248 This was confirmed by SWC data, showing both a lower soil water content in P_{con} systems
249 during half of the drought period and a faster decline of SWC in P_{con} (Table 3, Fig. 3).
250 During the imposed drought we observed a decrease of g_s for both species, which was
251 unaffected by neighbour identity at any time (Table 3, Fig. 4). The drier soils found in P_{con} did
252 therefore not cause the stomata of the P_{con} targets to close earlier.
253 At the end of the imposed drought, A_{sat} of *P. lanceolata* was lower in the drought treatment
254 than in the control treatment, irrespective of neighbour type (no treatment × neighbour
255 interaction; Table 2, Fig. 5). For *L. perenne*, on the other hand, the response of A_{sat} depended
256 on neighbour type (treatment × neighbour interaction), with a significant decrease of A_{sat}
257 observed for L_{het} during drought, while no significant effects of drought on maximum
258 photosynthesis were found for L_{con} (Table 2, Fig. 5).

259

260 **Discussion**

261 Our results demonstrate that a plant's response to abiotic stress can be affected not only by its
262 own inherent traits, but also to an important extent by the nature of its neighbours. Indeed,
263 both *Plantago lanceolata* and *Lolium perenne* suffered more from drought in terms of a lower
264 productivity if surrounded by more *Plantago* individuals or, from another point of view, by
265 less *Lolium* neighbours. We propose that several mechanisms potentially contribute to this
266 differential neighbour effect. First, the higher water consumption of *Plantago* compared to
267 *Lolium*, which caused a faster decrease of SWC in P_{con} than in P_{het}, could have been an
268 important driver. Although both species responded to soil drying by decreasing their stomatal
269 conductance, the faster decreasing SWC in P_{con} designs did not cause the stomata of those

270 targets to close earlier than P_{het} targets. This raises the question why aboveground biomass
271 was nevertheless more severely affected by the drought in P_{con} than P_{het} ? The fact that the
272 biomass of P_{het} targets did not decrease to a significant extent upon three weeks of drought,
273 may reflect that g_s only reached low levels ($< 200 \text{ mmol m}^{-2} \text{ s}^{-1}$) in the last 10 days of drought.
274 For P_{con} targets, the lower soil water availability presumably suppressed photosynthesis by
275 non-stomatal limitations such as inhibition of the internal CO_2 transport (Flexas et al., 2004;
276 Lawlor and Tezara, 2009) or down-regulation of the electron transport (Damour et al., 2009;
277 Llorens et al., 2003).

278 A second mechanism for the effect of neighbour composition on the drought response of the
279 *Plantago* targets may be found in the competitive behaviour of *Lolium*. This species has been
280 reported to suppress root production of several herbaceous species mainly in the top soil and
281 less in the deeper layers (Wardle and Peltzer, 2003). Although in our study the total root
282 production was not altered by neighbour composition, a higher presence of *Lolium* neighbours
283 may have displaced root production of the *Plantago* targets towards the deeper layers. As
284 observed in the analysis of SWC at three different depths, the soil dries faster at the top than
285 at the bottom. If *Plantago* targets indeed root deeper when surrounded by more *Lolium*
286 neighbours (as in P_{het}), prolonged access to soil water could ensue. Apart from a negative
287 impact of *Plantago* on the available soil water because of its greater water use, the differential
288 effect of the two species on their neighbours may therefore also have been caused by an
289 indirect positive effect of *Lolium* on water extraction. In a study on two desert grassland
290 species under drought conditions by Novoplansky and Goldberg (2001), one species as a
291 neighbour caused an increase in the root/shoot ratio of both target species compared to when
292 the other species was the neighbour. This is reminiscent of our suggestion that *Lolium* may
293 have displaced the roots of its neighbours.

294 Finally, for *Lolium*, SWC did not decrease significantly faster when growing together with
295 *Plantago*, although it too suffered from a lower productivity under drought (and a lower
296 maximum photosynthesis) in the presence of *Plantago*. We speculate that local horizontal
297 differences in SWC may have been involved. In a study on grass-shrub interactions,
298 neighbour species have been found to locally increase water availability through shading,
299 reducing evaporation (Maestre et al., 2003). Structural differences between species, here
300 between the more pending leaves of *Lolium* and the more erect *Plantago* leaves, may have
301 locally buffered soil drying in the L_{con} target positions.

302 One might expect that an individual would suffer less from drought when surrounded by
303 heterospecific neighbours than when surrounded by conspecific neighbours due to
304 complementarity. Obviously this not necessarily the case as the intrinsic absolute water
305 consumption of the neighbour might overrule any benefit from complementarity. Conversely,
306 having a high water consumer as a neighbour could be less negative than expected when its
307 roots extract water predominantly from a different soil zone than its heterospecific neighbours
308 and as consequence more of the total amount of soil water is used (Nippert and Knapp, 2007;
309 Verheyen et al., 2008). In this way, complementarity may diminish a negative effect (or
310 amplify a positive effect). As a consequence, selecting a different species pair with other traits
311 may yield different results.

312 Comparing the current study with others is difficult since most related experiments and
313 conceptual models focus on how gradients of resource availability modify plant-plant
314 interactions (Gaucherand et al., 2006; Goldberg and Novoplansky, 1997; Grime, 1979;
315 Tilman, 1988). When looking at the current study from this point of view one could conclude
316 that under control conditions neighbours determine the aboveground biomass of the targets
317 while under drought conditions neighbours have no impact (Fig. 2). However, no statistical
318 differences were detected between targets surrounded by conspecific or heterospecific

319 neighbours under control conditions for both species. Furthermore, it was our choice for the
320 current study to focus on the effect of plant-plant interactions on plant responses to
321 differences in resource availability, rather than on the opposite (the effect of resource
322 availability on interactions). In this way we concur with Brooker (2006), who stated that a
323 major challenge is to understand the role of plant-plant interactions in mediating the response
324 of natural systems to environmental changes. Disentangling the role of plant interactions can
325 help to clear the controversies on the role that plant diversity plays in the resistance to stress,
326 i.e. does greater plant diversity improve (Frank and McNaughton, 1991; Tilman, 1996;
327 Tilman and Downing, 1994) or reduce (Pfisterer and Schmid, 2002; Van Peer et al., 2004) the
328 system's resistance to stress? Recent studies have suggested that community composition may
329 be more important than plant diversity per se, but general mechanisms have not been found
330 (Baggs et al., 2003; Lawlor and Tezara, 2009; Prieto et al., 2009; Wilson, 2007). Studies like
331 this can be a catalyst in the search as to when diversity effects like complementarity are
332 overridden by species-specific effects. Future research efforts should encompass a wider array
333 of species to unravel the mechanistic basis needed for further upscaling and generalisation.
334 This is for example of relevance if plant-plant interactions are to be included in models that
335 predict ecosystem functioning in a future climate. Currently, bioclimatic or climate envelope
336 models relate species current geographic distributions to a set of current climatic factors,
337 using predicted future climate variables as inputs for these models to predict future
338 distributions. Unfortunately, these models largely ignore biotic relationships, in which the
339 distribution of one species is affected by the distribution of one or more other species (Lawler
340 et al., 2006; Pearson and Dawson, 2003).

341

342 **Conclusion**

343 This study demonstrates that drought responses of two target species may depend largely on
344 the identity and the traits (such as water consumption, rooting distribution) of the neighbours.
345 This finding illustrates that models to predict ecosystem functioning should take plant-plant
346 interactions into account. Then again, plant density could strengthen or weaken interactions,
347 so future experiments should also include this factor. Our study, together with similar studies
348 that explore traits such as plant fitness and seed production in the long term, can help to
349 elucidate how plant-plant interactions interact with changes in abiotic conditions in order to
350 more accurately project the structure and distribution of plant communities in a future climate.

351

352 **Acknowledgements**

353 This research was funded by the University of Antwerp as concerted research project
354 “Changes in the stress sensitivity of plants and ecosystems under climate change conditions”
355 (GOA-BOF-UA-2007). H. J. De Boeck is a post-doctoral research associate of the Fund
356 for Scientific Research - Flanders. We thank N. Calluy and M. Wellens for technical
357 assistance and H. Van De Velde for assistance in the field.

453 **Table 1** Details on measured parameters; above-ground (AG) biomass, root biomass, leaf
 454 area, stomatal conductance (g_s), light saturated net CO₂ assimilation rate (A_{sat}), volumetric
 455 soil water content (SWC); and details on the analyses of variance (ANOVA). Parameters were
 456 measured on the targets or on the whole community (target + neighbours; referred to as
 457 ‘total’). Day of year (DOY), number of chambers, number of replicates (rep) and number of
 458 repetitions (if applicable) are presented.

459

		start of drought DOY 197	during drought	end of drought DOY 217	ANOVA	
		8 chambers identical	4 chambers drought 4 chambers control		compare between...	fixed factors
AG biomass	target	/	/	2 reps/chamber	2 designs/species	treatment, neighbours
leaf area	total	1 rep/chamber	/	/	all 4 designs	design
root biomass	total	/	/	1 rep/chamber	2 designs/species	treatment, neighbours

461

462

463 **Table 2** Analysis of variance (ANOVA) of above-ground (AG) biomass of targets, root
 464 biomass of the communities and light-saturated net CO₂ assimilation rate (A_{sat}) of targets. The
 465 designs consist of a target species (*Lolium perenne* or *Plantago lanceolata*) either surrounded
 466 by six conspecific neighbours (con) or by three conspecific and three heterospecific
 467 neighbours (het). They were subjected to an imposed drought and a control treatment.
 468 Degrees of freedom (DF), F values and significance levels (p); p-values are presented in bold
 469 when significant (< 0.05). In case of a significant interaction the means of the treatments
 470 (drought vs. control) were compared between the two designs per target species with Tukey
 471 corrections for multiple comparisons; in case of non-significance of the interaction, the effect
 472 of treatment, irrespective of neighbour type, is presented.
 473

475

476

477 **Table 3** Analysis of variance (ANOVA) of volumetric soil water content (SWC), leaf area
478 and stomatal conductance (g_s). The experimental set-up consisted of 4 designs with a target
479 species (*Lolium perenne* (*Lp*) or *Plantago lanceolata* (*Pl*)) either surrounded by six
480 conspecific neighbours or by three conspecific and three heterospecific neighbours. The
481 designs were subjected to an imposed drought by withholding water for 20 days (day of year
482 (DOY) 197 - 217) and a control treatment. SWC was calculated as the mean at three different
483 depths (0, 20 and 4 cm). The course of SWC before and during the imposed drought was
484 compared between the four designs and between the measurement days, and if applicable,
485 between the different depths; leaf area was compared between the four designs; g_s at the start
486 of drought was compared between the two target species surrounded either by conspecific or
487 heterospecific neighbours; the course of g_s during drought was analysed for each target and
488 compared between neighbour composition and measurement days. Degrees of freedom (DF),
489 F values and significance levels (p); p-values are presented in bold when significant (< 0.05).
490

491

492 **Figure 1** Schematic presentation of the target-neighbour designs with control (C) and drought
493 (D) treatments. The drought treatment was obtained by withholding water for 20 days (day of
494 year (DOY) 197 - 217), whereas in the control treatment the watering regime was not
495 interrupted. White circles represent *Lolium perenne* individuals, grey circles represent
496 *Plantago lanceolata* individuals. The inner diameter of the containers is 19 cm and plants are
497 positioned at 5 cm interspace.

498

499 **Figure 2** Above-ground biomass of *Lolium perenne* (L) or *Plantago lanceolata* (P) target
500 plants subjected to an imposed drought and a control treatment. The targets were surrounded
501 by either six conspecific neighbours (con) or three conspecific and three heterospecific
502 neighbours (het). The drought treatment was obtained by withholding water for 20 days (day
503 of year (DOY) 197 - 217), whereas in the control treatment the watering regime was not
504 interrupted. Means \pm SE (n = 8). In each panel, bars that do not have a common letter differ
505 statistically (p < 0.05).

506

507 **Figure 3** Volumetric soil water content (SWC) of target-neighbour designs subjected to an
508 imposed drought by withholding water for 20 days (day of year (DOY) 197 – 217). The
509 designs consist of a target species (*Lolium perenne* (L) or *Plantago lanceolata* (P)) either
510 surrounded by six conspecific neighbours (con) or by three conspecific and three
511 heterospecific neighbours (het). SWC was calculated as the mean at three different depths (0,
512 20 and 40 cm; see Figure S1 and Table S1 for data and analyses). Means \pm SE (n = 8). A
513 posteriori analyses of the DOY \times design interaction show that SWC decreased fastest in P_{con}
514 and that SWC was lower in P_{con} than in the other designs on several days (p < 0.05 for each
515 comparison).

516

517 **Figure 4** Stomatal conductance (g_s) of *Lolium perenne* (L) or *Plantago lanceolata* (P) target
518 plants subjected to an imposed drought. The targets were surrounded by either six conspecific
519 neighbours (con) or three conspecific and three heterospecific neighbours (het). The drought
520 treatment was obtained by withholding water for 20 days (day of year (DOY) 197 - 217).

521

522 **Figure 5** Light saturated net CO₂ assimilation rate (A_{sat}) at the end of an imposed drought
523 (day of year 217), of *Lolium perenne* (L) or *Plantago lanceolata* (P) target plants. The targets
524 were surrounded by either six conspecific neighbours (con) or three conspecific and three
525 heterospecific neighbours (het). The drought treatment was obtained by withholding water for
526 20 days (DOY 197 - 217), whereas in the control treatment the watering regime was not
527 interrupted. Means \pm SE (n = 8). In each panel, bars that do not have a common letter differ
528 statistically ($p < 0.05$).
