Abstract

Aims: Structural and functional characterization of the globin coupled sensors (GCS) of *Azotobacter vinelandii* (AvGReg) and *Bordetella pertussis* (BpeGReg).

Results: UV/Vis and RR spectroscopies confirm the presence in AvGReg and BpeGReg of a globin domain capable of reversible gaseous ligand binding. In AvGReg an influence of the transmitter domain on the heme proximal region of the globin domain can be seen, and k'_{CO} is higher than for other GCSs. The O₂ binding kinetics suggest the presence of an open and a closed conformation. As for BpeGReg, the fully oxygenated AvGReg show a very high DGC activity. The CO rebinding to BpeGReg indicates that intra- and intermolecular interactions influence the ligand binding. The globin domains of both proteins (AvGReg-Gb and BpeGReg-Gb*) share the same GCS fold, a similar proximal but a different distal side structure. They homodimerize through a G-H helical bundle as in other GCS. However, BpeGReg-Gb* shows also a second dimerization mode.

Innovation: This paper extends our knowledge on the GCS proteins and contributes to a better understanding of the GCSs' role in the formation of bacterial biofilms.

Conclusions: AvGReg and BpeGReg conform to the GCS family, share a similar overall structure but they have different properties in terms of the ligand binding. In particular, AvGReg shows an open and closed conformation that in the latter form will very tightly bind oxygen. BpeGReg has only one closed conformation. In both proteins, it is the fully oxygenated GCS form that catalyzes the production of the second messenger.

Introduction

Globin coupled sensors (GCSs) are heme-based molecules widespread in Bacteria and Archaea, consisting of chimeric proteins characterized by an N-terminal globin sensor domain coupled to a variety of C-terminal transmitter domains. Classification based on the function of the latter distinguishes: diguanylate cyclase (DGC), phosphodiesterase (PDE), histidine kinase, methyl-accepting chemotaxis and a transmembrane function (20,33).

The globin domain exhibits an efficient sensor function based on the reactivity of the heme iron atom (56,69). Its structure is a variant of the 3-over-3 helical fold with an extra N-terminal Z-helix and no D-helix (44,63,70,75). Binding of diatomic gaseous ligands causes a conformational change of the sensor domain that is transferred *via* a linker region to the transmitter domain, regulating its activity. A comprehensive model for a full-length GCS has been proposed for *E. coli* diguanylate cyclase DosC (*EcDosC*) (63), although the precise mechanism of signal transduction within the molecule has still to be elucidated further.

Most known GCS have a transmitter domain mainly consisting of a GGDEF domain with DGC activity. GCS with DGC (or PDE) activity produce (or degrade) cyclic-di-(3',5')-GMP (c-di-GMP), a key second messenger involved in the conversion from a free-living into a sessile-living bacterial population through biofilm formation (23,32,57) and modulation of pathogenic factors (53). Bacteria in a biofilm show resistance to antibiotics and the host immune system and often result in persistent and chronic diseases (16). As such, biofilms are considered an important medical and industrial issue and, consequently, GCS with DGC activity are becoming of increasing scientific interest. Two examples of such biofilm-forming bacteria with a GCS are *Azotobacter vinelandii* and *Bordetella pertussis*.

Azotobacter vinelandii is a Gram-negative, alginate-biofilm-producing bacterium, capable of diazotrophic growth and N-fixation in the presence of O₂ (48). As such it has economic importance and it is widely used as a research model system. Genomic analysis revealed the presence of a GCS (AvGReg) (55,64). AvGReg is a 472 residues soluble protein consisting of a 178 residues N-terminal globin sensor domain (AvGReg-Gb) and a 170 residues C-terminal GGDEF transmitter domain endowed with a DGC activity.

Bordetella pertussis is a Gram-negative, aerobic, biofilm forming bacterial pathogen (9,36,73). It is the causative of pertussis or whooping cough a highly contagious human disease that still causes, yearly, many deaths among children worldwide (World Health

Organization: <http://www.who.int/topics/pertussis/en/>). In the *Bordetella pertussis* genome, one GCS with gene regulating function has been identified, namely *BpeGReg* (3, 4). As *AvGReg*, *BpeGReg* is a di-domain molecule (475 residues) consisting of a globin-like sensor domain (residues:1-155) covalently attached by a linker region (residues:156-296) to a transmitter domain (residues: 297-475) with DGC activity. This enzymatic activity is regulated by ligand (O_2) binding to the sensor domain, product (c-di-GMP) binding to an inhibitory site (RxxD motive in the transmitter domain), and the oligomerization state (mono- di- or tetramer) of the full GCS protein (6,7,50,70). The participation of c-di-GMP in the process of biofilm formation of *BpeGReg* has been demonstrated *in vivo* (70). The iron bound O_2 is stabilized by a TyrB10 and SerE11 residue of the globin sensor domain. Dimerization of this domain involves the G and H helices (7,50).

AvGReg and *BpeGReg* not only merit scientific attention due to their respective economic and medical importance, but a thorough comparison of the structural and functional properties of these two molecules can contribute to a better understanding of the general role of GCSs in the signaling mechanism associated with the formation of bacterial biofilms. We have therefore combined different biochemical and biophysical techniques to unravel the structural-function relationship of these two proteins. The study involves the comparative analysis of the *AvGReg* and *BpeGReg* full-length molecules, their respective globin domains and some mutants (*AvGReg*YB10F and Cys-mutant *BpeReg**). In the latter notation, asterisk indicates the Cys-Ser mutation of Cys16, Cys45, Cys114 and Cys154, needed for crystallization purposes, see Materials and Methods for details. Moreover, the full-length *AvGReg* was for the first time obtained *via in-vivo* folding, which led to a molecule with marked differences in the ligand binding properties than reported earlier for *in-vitro* folded *AvGReg* (from now on referred to as ⁺*AvGReg*) (64).

Results

UV/Vis spectroscopy

The absorbance maxima of the UV/VIS spectra of full-length *AvGReg* and *BpeGReg*, in different ligation forms are reported in Table 1. The spectra of the 'as purified' forms are typical for low-spin O_2 -ligated ferrous globins, while those of the reduced forms are characteristic for ferrous high-spin pentacoordination of the heme. The absorbance maxima do not change for the truncated proteins consisting only of the globin domains

(AvGReg-Gb and *BpeGReg*-Gb), nor for the Cys mutant (*BpeGReg**) and the YB10F mutant of AvGReg (data not shown). Overall these results confirm the presence of a globin domain capable of gaseous ligand binding and they are comparable to what was already reported for GCS in the literature (50,70).

Resonance Raman spectroscopy

The resonance Raman (RR) spectra for AvGReg(-Gb) and *BpeGReg*(-Gb) were recorded in the as-purified (O₂-bound ferrous) state, and in the dithionite-reduced (deoxy ferrous) state (Fig. 1). The corresponding spectra of *BpeGReg** and *BpeGReg*-Gb* are depicted in Figure S1. The high frequency region (1300-1800 cm⁻¹) of the spectrum provides insights on the oxidation (ν_4), coordination (ν_3), and spin (ν_2) states of the heme iron atom (59) (Fig. 1B,D, Table 2). The observed marker frequencies are in accordance with those reported for SwMb (60,61) and different gas sensor proteins, such as the *Bacillus subtilis* heme-based aerotaxis transducer (*BsHemAT*) (2), the isolated globin domain of *EcDosC* (*EcDosC*-heme) (28), and the globin-coupled histidine kinase from *Anaeromyxobacter* sp. Fw109-5 (*AfGcHK*) (29) (Table 2). They confirm the assignment of the ferrous form of AvGReg(-Gb) and *BpeGReg* to a high-spin pentacoordinated heme site. The as-purified proteins are all in the O₂-ligated ferrous form. Interestingly, the RR spectrum of *BpeGReg* (Fig. 1D,a) reveals partial photolysis of the O₂ ligand (two ν_4 bands at 1359 cm⁻¹ and 1373 cm⁻¹, agreeing with the deoxy and oxy ferrous form). The partial photolysis hampers the analysis of the low-frequency part of the RR spectra of O₂-*BpeGReg*, which will therefore not be considered in the below discussion.

The low frequency region (200-900 cm⁻¹) reveals in-plane and out-of-plane vibrational modes of the heme (59). The $\nu_{\text{Fe-His}}$ is observed at 227 cm⁻¹ for the ferrous unligated AvGReg (Fig. 1A,b). This value is similar to that of ferrous *BsHemAT* (225 cm⁻¹) (2) and *EcDosC*-heme (227 cm⁻¹) (28). The $\nu_{\text{Fe-His}}$ peak broadens and shifts to ~214 cm⁻¹ for AvGReg-Gb (Fig. 1A,d). For all deoxy ferrous *BpeGReg** and *BpeGReg*-Gb* forms, the $\nu_{\text{Fe-His}}$ mode is observed as a broad peak around 229-233 cm⁻¹ (Fig. 1C,b,d, Fig. S1Ab,d). The $\nu_{\text{Fe-His}}$ stretching mode is known to depend on different parameters (2,39,43). The higher $\nu_{\text{Fe-His}}$ mode found in ferrous unligated AvGReg and *BpeGReg* can indicate a stronger H-bonding to the proximal His N^δ nitrogen, less strain on the Fe-His bond, and/or a smaller dihedral angle ϕ between imidazole plane and the nearest N(pyrrole)-Fe-N(pyrrole) axis. Thus, in

keeping with the sensor functionality, the $\nu_{\text{Fe-His}}$ difference observed between AvGReg and AvGReg-Gb points to an influence of the signaling domain on the heme proximal region of the globin domain. Similarly, the γ_7 pyrrole bending mode, observed usually between 288 - 313 cm^{-1} in heme proteins and indicative of an out-of-plane distortion of the heme, changes slightly from a sharp peak at 301 cm^{-1} for deoxy AvGReg to a broadened peak at 299 cm^{-1} for deoxy ferrous AvGReg-Gb (Fig. 1A). This is also found for the deoxy form of horse heart Mb (302 cm^{-1}) (25). In both cases, O_2 ligation causes a reduction of the out-of-plane distortion (less pronounced γ_7 mode). A similar trend is observed for the γ_7 bending modes of BpeGReg(-Gb) (Fig. 1C).

The heme propionate and vinyl modes reveal important information about the stabilization of the heme by the surrounding protein. The vinyl $\delta(\text{C}_\beta\text{C}_\alpha\text{C}_{\beta 2,4})$ bending modes more or less coincide and give rise to broadened peaks around 421, 414 and 417 cm^{-1} for O_2 -BpeGReg-Gb, O_2 -BpeGReg* and O_2 -BpeGReg-Gb*, respectively (Fig. 1C,c, Fig. S3A,a,c). This indicates that the out-of-plane distortions influence each of the pyrrole units in a similar way (68). The increase in wavenumber of this mode for the globin domain compared to the full length domain, indicates an effect of the transmitter domain on the globin domain. This effect was not observed for the AvGReg proteins (415 cm^{-1} (Fig. 1Aa,c)). Deoxygenation leads for BpeGReg* and BpeGReg-Gb* to $\delta(\text{C}_\beta\text{C}_\alpha\text{C}_{\beta 2,4})$ bending modes at 412 cm^{-1} , whereby the peaks are clearly less broad than in the case of the oxygenated proteins (Fig. 1C, Fig. S1). This means that O_2 ligation influences the stabilization of the two vinyl groups in a different way. Again, this effect is far less pronounced in the AvGReg case (Fig. 1A).

O_2 -AvGReg and O_2 -AvGReg-Gb display the $\delta(\text{C}_\beta\text{C}_\alpha\text{C}_d)$ propionate bending mode at 381 cm^{-1} and 377 cm^{-1} , respectively (Fig. 1Aa,c), while those of O_2 -BpeGReg-Gb, O_2 -BpeGReg* and O_2 -BpeGReg-Gb* are found at 382, 375 and 378 cm^{-1} , respectively (Fig. 2C,c, Fig. S1A,a,c). This suggests a moderate to strong electrostatic interaction of the heme propionate groups with the surrounding amino-acid side chains. Interestingly, the $\delta(\text{C}_\beta\text{C}_\alpha\text{C}_d)$ mode is found at 363 cm^{-1} for ferrous AvGReg, and 380 cm^{-1} for ferrous AvGReg-Gb, respectively. The former low value reflects the pronounced effect of the second domain on the heme surrounding upon ligand binding. While this mode is still clearly detectable for the deoxy ferrous state of AvGReg(-Gb) (Fig. 1A,b,d), the $\delta(\text{C}_\beta\text{C}_\alpha\text{C}_d)$ mode

can only be weakly observed for deoxy ferrous *BpeGReg*-Gb (Fig. 1Cd, small peak at 379 cm^{-1}).

For the *in vivo* folded O_2 -AvGReg and O_2 -AvGReg-Gb, two $\nu_{\text{Fe-O}_2}$ modes were found (Fig. 1Ab,d, Table 2). The first mode is located at 563 cm^{-1} (561 cm^{-1}), while the second mode is located at 573 cm^{-1} (see Fig. S2, for a details of this spectral region in the RR spectrum of O_2 -AvGReg). The 573 cm^{-1} mode is similar to the one observed for other globins, such as Mb which show $\nu_{\text{Fe-O}_2}$ around 570 cm^{-1} (12,24,27,58). Lower Fe- O_2 stretching modes of 557-560 cm^{-1} have been found for the oxygenated forms of *BsHemAT* (2) and *AfGCHK* (29) (Table 2). In this respect, previous studies on *Mycobacterium tuberculosis* (74) and *Chlamydomonas eugametos* 2/2Hbs (11) indicate that the low $\nu_{\text{Fe-O}_2}$ mode is related to a strong hydrogen bond between the bound O_2 molecule and residue TyrB10. As such, this low $\nu_{\text{Fe-O}_2}$ mode suggests a strong stabilization of the bound O_2 through hydrogen bonding in AvGReg, while the 573 cm^{-1} indicates the co-existence of a more open configuration in which the O_2 is not stabilized. For the oxygenated *BpeGReg** variants, only a $\nu_{\text{Fe-O}_2}$ mode in the 556-560 cm^{-1} region is found (Table 2, Fig. 1, Fig. S1), indicating that the O_2 ligand is strongly hydrogen bonded to distal amino-acids with no open conformation present. This will be shown to correlate with the kinetics data. A very recent FTIR study on the CO-ligated ferrous *BpeGReg* and its Tyr43Phe variant revealed that one of the CO-bound conformers is strongly hydrogen-bonded to the distal Tyr(43)B10, in line with the here observed H-bonding of the O_2 ligand (51).

In earlier work, we already performed RR analyses on $^{\dagger}\text{AvGReg}$ (-Gb) (64). While the RR data obtained in both studies are similar for the globin domain of the protein, the RR and electron paramagnetic resonance data of $^{\dagger}\text{AvGReg}$ showed the protein to be in the ferric form due to the *in-vitro* refolding. Figure S3 (supplementary material) shows the optical absorption and RR data for AvGReg oxidized with ferricyanide. It shows that (partial) oxidation of the protein can be obtained chemically, but that it also leads to partial denaturation of the protein as can be derived from the optical absorption peak at 646 nm. The spectra in Figure S3 for oxidized AvGReg agree with those previously obtained for $^{\dagger}\text{AvGReg}$, where also signs of partial denaturation were found (64).

Ligand binding kinetics on AvGReg proteins

AvGReg proteins and the AvGReg YB10F mutant were characterized in terms of the CO and O₂ binding equilibria and their kinetics as described in Materials and Methods. In the whole CO concentration range explored in the flash-photolysis experiments, the time courses of the CO binding to AvGReg can be described by a single exponential, allowing the use of a minimum reaction mechanism (Scheme 1, Materials and Methods (64)). The value of the kinetic parameter that defines CO binding ($k'_{\text{CO}} = (0.48 \pm 0.01) \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) is very similar to the value reported for SwMb (Table 3; Fig. 2). Only a minor influence is noticed of the protein truncation or YB10F mutation. However, the other GCSs characterized to date show a very moderately (*BsHemAT*) to significantly lower (*EcDosC* and *AfGCHK*) CO association rate constant (Table 3).

The results of the flash-photolysis O₂/CO competition experiment can be described with a second order reaction mechanism (see Materials and methods, Scheme 2). The O₂ association/dissociation rate constants of AvGReg, as well as the constant for CO dissociation from AvGReg (Table 3; Fig. 2C,D), have been determined using Equations 1 and 2 (see Materials and methods). Interestingly, stopped-flow measurements reveal the presence of a second phase in the O₂/CO replacement mechanism (Table 3; Fig. 2B). Therefore, we can conclude that AvGReg is characterized by a fast O₂ binding ($k'_{\text{O}_2} = (12.2 \pm 1.5) \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) and two O₂ dissociation constants ($k_{\text{O}_2} = (1732 \pm 377) \text{ s}^{-1}$ and $k_{\text{O}_2} = (0.53 \pm 0.05) \text{ s}^{-1}$).

The O₂ association and dissociation rate constants we present here for the AvGReg differ significantly from the ones measured previously for the *in vitro* refolded protein [†]AvGReg (Table 3). In particular, [†]AvGReg appears to release dioxygen 160 times slower (high k_{O_2}) and 1.3 times faster (low k_{O_2}).

While two distinct k'_{O_2} values were measured for *AfGCHK* (29), a biphasic O₂ dissociation was observed for *BsHemAT* (75) as for AvGReg (Table 3). A difference of more than 200 fold is revealed when comparing the higher K_{d} values of AvGReg and *AfGCHK*, while the lower K_{d} values are in the same order of magnitude for the two GCSs. This indicates the presence of an extremely stable Fe-O₂ complex in both cases. In contrast, we find that the higher K_{d} value of AvGReg and *BsHemAT* are in the same order of magnitude, while the lower K_{d} of AvGReg is 100 times smaller than that of *BsHemAT*. The latter

observation highlights the very high O₂ affinity of AvGReg, being the highest among the other globin sensors characterized to date, suggesting that it can be (and remain) activated in the presence of traces amounts of O₂.

A likely explanation of these results lies in the observation of two $\nu_{\text{Fe-O}_2}$ modes for O₂-ligated AvGReg in solution, linked to an *open* and *closed* conformation for the O₂ stabilization, responsible for the two dissociation constants, similarly as for BsHemAT (75). Within this model, when the globin domain is in the *open* conformation, O₂ is less stabilized inside the heme pocket, allowing a more efficient diffusion of CO from the outer environment, and faster O₂ displacement. On the other hand, in the *closed* conformation, O₂ is firmly bound in the heme pocket, and well protected from the solvent. The competition between O₂ and CO is impaired, thus O₂ displacement is significantly slower. The results for AvGRegYB10F indicate that Tyr(44)B10 plays an important role in this regulation (Table 3, Fig. S4). Not only does the fastest O₂ dissociation rate increase with an order of magnitude upon mutation, the dissociation rate from the *closed* confirmation increases with a factor of ~300.

Ligand binding kinetics on *Bordetella pertussis* proteins

The ligand binding parameters for CO and O₂ binding to BpeGReg and BpeGReg-Gb, are summarized in Table 3 and Fig. 3. Interestingly, the CO binding reactions of BpeGReg and the isolated BpeGReg-Gb show a different decay. The double exponential rebinding to BpeGReg is defined with $k'_{\text{COfast}} = 0.60 \mu\text{M}^{-1} \text{s}^{-1}$ and $k'_{\text{COslow}} = 0.01 \mu\text{M}^{-1} \text{s}^{-1}$, while the rate constant of the BpeGReg-Gb single exponential reaction is $k'_{\text{CO}} = 0.11 \mu\text{M}^{-1} \text{s}^{-1}$. The explanation for this difference must be related to the presence of the transmitter domain, though we believe it goes beyond the mere structural effect of the absence/presence of this domain, as no major modification of the heme environment can be ascribed to the isolated globin domain. Considering also the dimerization process, we confirm the data by Rivera *et al.* (50) that the intra- and intermolecular interactions influence the ligand binding capabilities and, therefore, result in this CO affinity difference. Surprisingly, recent FTIR of BpeGReg-Gb and BpeGReg showed three CO stretches in both proteins, corresponding to an open and a closed (H-bonded) conformation and a pH-dependent conformer stabilized by structural water (51).

The O₂/CO competition studies and the O₂ association/dissociation rate constants of *BpeGReg* have been determined as for *AvGReg*. With $k'_{O_2} = 24.02 \mu\text{M}^{-1} \text{s}^{-1}$ and $k_{O_2} = 4.0 \text{s}^{-1}$ (Table 3), *BpeGReg* is capable of selective and more efficient O₂ binding when a gas mixture is present, as is also the case for myoglobin (1). Moreover, the low K_d values for O₂ ($K_d = 0.17 \mu\text{M}$) indicate that this sensor will be saturated with O₂ in physiological conditions. This is in line with the RR data that reveal only one $v_{\text{Fe-O}_2}$ mode agreeing with a strong hydrogen bonding and thus stabilization of the dioxygen ligand. Despite the fact that the reported k'_{O_2} from Wan *et al.* (70) is lower, the results are in accordance with the reported transmitter domain activation *via* O₂ binding to the sensor domain (70). Indeed, the very high affinity of the full-length *BpeGReg* suggests that this characteristic ensures a stable promotion of the *BpeGReg* DGC activity, resulting in the typical chronic infection-related biofilm persistence (6,7,50,70).

Diguanylate cyclase activity of AvGReg

We measured and analyzed the DGC activity of *AvGReg* to complement the already published data on *BpeGReg* (7,70). By means of an optimized DGC activity assay, we could collect reproducible time point series within few seconds from time zero to confidently determine the initial reaction rate. We tested numerous substrate concentrations, which revealed a high sensitivity of O₂-*AvGReg* to product inhibition, as already reported for *BpeGReg* and *EcDosC* (28, 70). To avoid bias due to this effect, we determined the enzyme specificity constant (calculated as k_{cat}/K_m) at GTP concentrations where no product inhibition was detected as described in Material and Methods (Fig. 4) and no cooperativity was seen.

For the oxygenated form of the *in vivo* folded *AvGReg*, the reaction reached completion after 20 minutes for all the substrate concentrations used (20 to 65 μM GTP) (data not shown), yielding a k_{cat}/K_m value of $(1.13 \pm 0.13) \times 10^4 \text{M}^{-1} \text{s}^{-1}$. O₂-*BpeGReg* shows a 66 fold lower enzyme specificity as published by Burns *et al* ($k_{\text{cat}}/K_m = 0.17 \times 10^3 \text{M}^{-1} \text{s}^{-1}$) (6) with completion reached after 30 minutes, while *EcDosC* is characterized by a high autoxidation rate that hindered the estimation of the exact turnover number (28). The ferrous unligated form of *AvGReg* was also assayed for DGC activity. Comparison of the O₂-*AvGReg* and unligated *AvGReg* catalyzed reactions showed that in the latter case c-di-GMP synthesis is 50% decreased (Fig. 4), as previously reported also for *BpeGReg* and *EcDosC*

(28,70). These results confirm the role of O₂ as DGC reaction trigger for this class of GCSs. Considering that *A. vinelandii* does not grow anaerobically and the very high O₂ affinity of AvGReg, it is likely that in physiological condition the AvGReg sensor is in the O₂-bound active state already in the presence of traces amounts of O₂.

*Tertiary and quaternary structures of AvGReg-Gb and BpeGReg-Gb**

The ferric aquo-met form of AvGReg-Gb and *BpeGReg-Gb** crystal structures have been determined at 2.83 Å and 3.20 Å resolution, respectively (two molecules per asymmetric unit, referred to as A and B in both cases). The final AvGReg-Gb model consists of 258 amino acids; no electron density is observed for residues 48-67 and 46-69 in chains A and B, respectively (B-C-E region). The refined *BpeGReg-Gb** structure comprises 306 amino acids; only residues 57-63 in chains B (C-E loop) show poor electron density. Data collection and refinement statistics are reported in Table 4.

The overall fold of AvGReg-Gb and *BpeGReg-Gb** conform to the modified globin fold typically found for GCS sensor domains (44,63,75) and protoglobin (40,45,46), consisting of 8 helices which, according to the classical globin nomenclature, have been named in alphabetical order from A to H, with a Z helix preceding the A at the N-terminus and the D helix absent (Figs. 5A,B). The two AvGReg-Gb and *BpeGReg-Gb** structures superimpose well, with a root mean squared deviation (rmsd) of ~1.3 Å over 126 Cα atom pairs, with structural differences localized at the N-terminal region (including the Z helix), in the B-E region, in the EF and GH loops (Fig. 5C).

Overall, two major features, both associated to the heme pocket, uniquely characterize AvGReg-Gb. On the heme-proximal side AvGReg-Gb exhibits one of the longest F-helix seen in globins (23 residues); this is due to the fact that the N-terminus of the F helix contains one more turn at the expense of the C-terminal turn of the E helix (Fig. 5A,C). On the heme-distal side the structural disorder at the B-C-E region (in both the A and B chains) results in the unwinding of almost the whole B-helix (Fig. 5A). The B-C-E region is instead well structured in *BpeGReg-Gb** (Figs. 5B,C).

The AvGReg-Gb and *BpeGReg-Gb** monomers assemble in homodimers with the interface residues belonging to the Z, G, and H helices of both A and B chains (Fig. 6A,B). Thus, the dimerization interface has a four α-helical G-H bundle as the core region (including 11 H-bonds and 7 salt bridges for AvGReg-Gb, and 11 H-bonds and 16 salt

bridges for *BpeGReg-Gb**), while the adjacent Z helices provide mostly van der Waals interactions. The dimeric assembly observed in *AvGReg-Gb* and *BpeGReg-Gb** is similar to those found in *GsGCS*¹⁶² (PDB code: 2W31) (44), *BsHemAT* (PDB codes: 1OR4, 1OR6) (75), *EcDosC* (PDB code: 4ZVA, 4ZVB) (63), and in *MaPgb* (PDB codes 2VEB, 2VEE) (40). However, the dimeric interface surface area can vary significantly: it is large for *MaPgb* (~2,100 Å²), *BsHemAT* (~1,800 Å²) and *GsGCS*¹⁶² (~1,700 Å²), medium for in *EcDosC* (~1,300 Å²) and *AvGReg-Gb* (1,304 Å²), and only 1,042 Å² for *BpeGReg-Gb**.

Furthermore, the precise orientation of the A/B subunits in the dimer is not the same in different GCS proteins. Indeed, when the *AvGReg-Gb* A chain is superimposed to that from the other GCSs, the match with the B chain is good for *BpeGReg-Gb** and *EcDosC*, while the *BsHemAT* B chain is rotated by ~20°, and *GsGCS*¹⁶² and *MaPgb* by ~30°, around an axis approximatively orthogonal to the G-H helices. Strikingly, a similar (albeit more pronounced, ~60°) different orientation of the subunits of the dimer has been found in another *BpeGReg-Gb** crystal form (same spacegroup *C2*, but different unit cell), determined at 1.55 Å resolution (*BpeGReg-Gb*-2*) (Table 4). This second quaternary structure is symmetrical around a crystal axes, covers a contact surface of 1,305 Å² (similar to *AvGReg-Gb* and *EcDosC*) with 14 hydrogen bonds and 10 salt bridges, and involves the Z, G, and H helices, and the CE corner (Fig. 6C,D).

It should be noted that the different dimerization mode cannot be ascribed to a different structure of the interfacing monomers, since the *BpeGReg-Gb** and *BpeGReg-Gb*-2* structures don't show significant deviations if compared monomer by monomer (rmsd values ranging between 0.50 Å and 0.80 Å, over 138-145 Cα pairs). The different quaternary assembly is most likely responsible for the minor structural deviations observed at the N-terminus of the E helix, in the FG, G, GH, and H regions between the *BpeGReg-Gb** and *BpeGReg-Gb*-2*. In particular, the C-terminal His155 residue, buried at the dimeric interface in *BpeGReg-Gb**, is solvent exposed in *BpeGReg-Gb*-2* and interacting with an additional heme group (probably released in solution by a fraction of *BpeGReg-Gb**) which becomes hexacoordinated between the end of two H-helices at the top of the dimeric interface (Fig. 6E,F).

Heme proximal side

AvGReg-Gb and *BpeGReg-Gb** share a very similar heme pocket proximal side, due to a very high sequence similarity in this protein region. The proximal heme pocket is lined by residues Ile(97)F4, Ile(100)F7, Ile(104), Ile(106), Val(111)G4, and Met(154)H17 in AvGReg-Gb, and Val(95)F4, Val(98)F7, Ile(102), Ile(104), Val(109)G4, and Met(153)H17 in *BpeGReg-Gb**, which surround and mostly contact the porphyrin ring.

Both AvGReg-Gb and *BpeGReg-Gb** show a loose coordination bond between the Fe atom and the proximal His residue with Fe–His(101)F8 NE2 distance of 2.39 Å and 2.50 Å in the A and B monomers of AvGReg-Gb, and Fe–His(99)F8 distance of 2.10 Å and 2.29 Å in A and B chains of *BpeGReg-Gb**. In AvGReg-Gb and *BpeGReg-Gb** the F8 imidazole ring lies in a staggered azimuthal orientation relative to the heme pyrrole N-atoms in chain A, and it is eclipsed in chain B along the direction of the heme pyrrole NA-NC atoms in AvGReg-Gb and NB-ND in *BpeGReg-Gb** (Fig. 7A). In the *BpeGReg-Gb*-2* His(99)F8 stabilizes the heme iron atom with a distance of 2.20 Å in chain A and 2.14 Å in chain B, being always eclipsed along the direction of the heme pyrrole NB and ND atoms.

Heme distal side

The heme distal side of AvGReg-Gb and *BpeGReg-Gb** varies considerably, but both reveal a high conformational flexibility of the B-C-E region. In AvGReg-Gb the heme distal pocket residues Tyr(42)B8, Phe(43)B9, Tyr(44)B10, and Leu(70)E11 surround a heme-ligated water molecule (2.81 Å and 3.32 Å in the A and B chains, respectively), which is not stabilized by any polar interaction provided by the protein (Fig. 7A). It should be noted, however, that part of the heme-distal site corresponding to the B-C-E region (residues 48-67 and 46-69 in chain A and chain B, respectively), could not be modeled due to the low connectivity of the experimental electron density map. In particular, this disordered region involves the C-terminal end of the B-helix, which in AvGReg-Gb appears to be almost completely unwound (Fig. 5A). As a consequence, Tyr(44)B10, a conserved residue usually involved in ligand stabilization in GCS proteins, is too far to H-bond the heme-bound water molecule (Fig. 7A). The same considerations hold for the nearby Tyr(42)B8, an amino acid which is instead specific of AvGReg-Gb and few others GCSs (19). However, both Tyr residues point their hydroxyl groups towards the interior of the distal site and, therefore, could be involved in ligand stabilization in the context of a structured B-C-E region.

Conformational disorder at the BE distal site region has been previously reported in GCSs and other globins, and, in some cases, associated to functional roles. For instance, in GCSs and related proteins (*i.e.* protoglobin) disorder in this region has been associated to multiple conformations of specific residues whose side-chain orientations in the heme-distal site depend on the ligation state of the heme-Fe atom (40,44,45,46,75). However, in AvGReg-Gb the disordered region is delimited by residues Gly(40)B6-Pro(41)B7 on one side and Gly(68)E9 on the other, which are specific for AvGReg-Gb and not conserved in other GCSs (19,44).

The *BpeGReg-Gb** heme iron atom coordinates to a water molecule (at 3.06 Å in the A chain and at 2.90 Å in the B chain) at the distal site, which is not stabilized by any interaction with the amino acids facing the distal site. In particular, Tyr(43)B10 is pointing its hydroxyl group towards the exterior of the distal site. The distal site residues are hydrophobic (Phe(42)B9, Leu56, Val(61)E3, Leu(65)E7, Met(69)E11) and well defined in the A chain of the dimer, while in the B chain the C-E region (residues 57-60) is partly disordered (Fig. 7B). Interestingly, the second crystal form, *BpeGReg-Gb*-2*, shows an Fe-coordination state at the distal site that differs in the A and B chains and from the *BpeGReg-Gb** crystal form: the heme-Fe is loosely hexacoordinated to Tyr(43)B10 (3.11 Å) in chain A, (Fig. 7C) and to an imidazole molecule (2.12 Å), probably originating from the purification protocol, in chain B, with Tyr(43)B10 swinging out from the distal site due to steric repulsion caused by the imidazole ligand (Fig. 7D). Overall, we can conclude that the different dimerization mode of *BpeGReg-Gb*-2* has an impact in the distal site geometry reshaping, with Tyr(43)B10 able to point inwards and outwards, in keeping with the previously proposed mechanism whereby the globin domain dimerization leads to conformation(s) of the distal pocket that adjust the position of the hydrogen bonding residues involved in O₂ dissociation kinetics (50). Interestingly, the distal site swinging movement of TyrB10 has been suggested as the mechanism of O₂ stabilization for other GCSs, as *BsHemAT* (75) and *EcDosC* (63).

In *BpeGReg-Gb** the heme group's propionates are not interacting with Lys(64)E6 at the distal site, nor with Lys(94)F3 at the proximal site (Fig. 7A), while in the *BpeGReg-Gb*-2* structure only a loose interaction is present with Lys(64)E6 (Fig. 7C,D).

Discussion

The *A. vinelandii* and *B. pertussis* are highly interesting bacterial systems. Indeed, *A. vinelandii* fixes N₂ in the presence of O₂, a unique metabolic feature that renders it particularly interesting for industrial applications whereas *B. pertussis* is a highly contagious human pathogen that still causes many deaths worldwide and is, therefore, of considerable medical interest. In addition, the GCS of both systems are involved in biofilm formation. In this respect, their characterization, here presented, is significant for a more detailed understanding of the control that the sensors might exert on biofilm formation.

The combination of biochemical techniques applied in this study provides complementary pictures of AvGReg and BpeGReg functional and structural behaviors. We performed our experiment on *in vivo* folded full-length proteins. It is important to note that in the previously published study on AvGReg and AvGReg-Gb, both proteins had been purified from inclusion bodies, followed by *in vitro* refolding (64). The high level of agreement between our data and the optical and RR spectra of the *in vitro* refolded AvGReg-Gb is an indication of the reliability of the refolding method when applied to the globin domain alone. In contrast, the discrepancies detected between *in vivo* folded AvGReg and that purified from inclusion bodies strongly suggest that the presence of the second (transducer) domain may hamper a correct *in vitro* refolding process.

We showed that both the *in vivo* folded AvGReg and BpeGReg sensors are oxygenated when purified and pentacoordinated when the deoxy ferrous species is produced through dithionite reduction. Additionally, based on our enzymatic *in vitro* assays and the literature, we proved that O₂ binding triggers c-di-GMP biosynthesis and that O₂-AvGReg and O₂-BpeGReg are the catalytically competent forms. O₂-AvGReg and O₂-BpeGReg display a high sensitivity to product inhibition confirming the literature (70). For O₂-AvGReg and O₂-BpeGReg a k_{cat}/K_m value of $1.13 \pm 0.13 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$ (reported here) and $0.17 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ (6,7) was obtained, respectively. The RR measurements indicate that the heme pocket of the fully oxygenated proteins are well structured, with moderate to strong electrostatic interactions of the heme propionate groups with the surrounding amino-acid side chains and the O₂ molecule tightly bound to the heme-Fe for all forms and an additional more open distal heme-pocket site for O₂-AvGReg. These data are confirmed by the recently published structure of the oxygenated form of BpeGReg-Gb (structure not yet

released by PDB), where O₂ is described as tightly bound to the Fe²⁺ and H-bonded to Tyr(43)B10, and Lys(64)E6 forms a hydrogen bond with heme propionate (51).

The combination of kinetics measurements and the structural data suggest mechanisms for protein activation and signal transduction. In the case of AvGReg the kinetics measurements reveal a fast O₂ association ($k'_{O_2} = 12.2 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$) and a biphasic O₂ dissociation, characterized by fast and slow rates ($k_{O_2} = 1732$ and 0.53 s^{-1} , respectively). Among GCSs a biphasic O₂ dissociation has been reported only for BsHemAT (75). The higher K_d for O₂ is in the same order of magnitude for the AvGReg and BsHemAT, while the lower K_d highlights the very high O₂ affinity of AvGReg, being the highest among the other globin sensors characterized to date (see Table 3), suggesting that it can be activated in the presence of traces amounts of O₂. The crucial role of Tyr(44)B10 is highlighted by the binding kinetics study of the YB10F mutant which shows a significant increase of O₂ dissociation rate, for both the fast and slow rates (Table 3). Specific high affinity O₂ binding (needed for sensing, transport, and storage) requires significant deviation from the sliding scale rule, which predict that, although the equilibrium dissociation constants (K_d) can vary a lot, the ratios for NO:CO:O₂ binding are roughly the same, namely 1:~10³:~10⁶ when the proximal ligand is a histidine and the distal site is apolar (66). Indeed, data reported for GCSs (including BpeGReg) show that, in general, CO affinity is higher than O₂, but that the $K_D(O_2)/K_D(CO)$ ratio is much smaller than that predicted by the sliding scale rule due to a preferentially lower $K_D(O_2)$ associated with hydrogen bonding stabilization of the O₂ molecule into the distal site (66).

Within this picture the biphasic behavior for AvGReg O₂ dissociation, measured by flash-photolysis O₂/CO competition, can be explained by the presence of two different AvGReg conformations (*open* and *closed*, respectively) responsible for the two dissociation rate constants. More precisely, when the globin domain is in the *closed* conformation, O₂ would be firmly bound in the heme pocket and well protected from the solvent. As a result, the competition between O₂ and CO would be hampered and O₂ displacement significantly slower. On the contrary, when the protein is in the *open* conformation, O₂ would be less stabilized within the heme pocket, thus allowing a more efficient diffusion of CO from the outer environment and faster O₂ displacement. Both conformations are in keeping with the RR measurements on the fully oxygenated ferrous AvGReg. All in all, the

crystal structure of the AvGReg-Gb ferric form reveals that the B-C-E region can undergo to structural disorder, probably favoured by the Gly-rich sequence at the BE region boundaries (not present in other GCSs), and this protein flexibility is compatible with the presence of an *open* conformation. From RR and kinetics follows that there is a second more closed (and probably more rigid) conformation that is not populated in the crystals. This closed conformation involves Tyr(44)B10.

Furthermore, the presence of the transmitter domain in the full-length AvGReg relaxes the heme proximal coordination when compared to the isolated AvGReg-Gb sensor domain. Indeed, the aquo-met crystal structure is in keeping with the RR measurements on the ferrous unligated protein, indicating a staggered conformation of the proximal His(127)F8 side chain and, therefore, a higher strain on the Fe-His bond for the isolated globin domain relative to the full-length protein. Such relaxation at the F-helix proximal His(127)F8 may be also part of the signal transduction mechanism between domains upon O₂ binding.

In contrast to AvGReg, no dramatic change in the sensor domain of BpeGReg can be ascribed to the absence/presence of the transmitter domain. Indeed, the RR spectra measured on BpeGReg-Gb and BpeGReg (and their BpeGReg-Gb* and BpeGReg* Cys-mutants) are very similar. This suggest that the signal transduction mechanism for the BpeGReg globin domain activation involves structural modifications in protein regions far from the heme pocket. The measured k'_{O_2} and k_{O_2} values suggest that BpeGReg is capable of selective and more efficiently binding O₂ when a gas mixture is present, as is also the case for myoglobin (1). The low K_d (O₂) values indicate that, under physiological conditions, the sensor will permanently bind O₂. A biphasic behavior for O₂ dissociation, as seen for AvGReg, is not recorded for BpeGReg, in line with the RR observation of only one (*closed*) conformation for the stabilization of the distal O₂ ligand. However, flash photolysis experiments indicate that the CO binding kinetics differs between the isolated BpeGReg-Gb (one exponential) and the full-length BpeGReg (two exponential). This result proves that the overall protein dynamicity changes when the transmitter domain is present, probably due to the presence of structural interactions between sensor and transmitter domains, likely at the oligomerization interface, necessary for the signal transduction process as also seen by Rivera et al (50).

Finally, the crystal structure of the aquo-met form of *BpeGReg-Gb** shows that the water ligand is not stabilized by any distal residue, the Tyr(43)B10 hydroxyl group is pointing away from the heme distal side, and the propionates are not interacting with the protein. These data provide a complementary picture of the recently published O₂-bound structure (PDB code: 6M9A) (51) where, instead, the strong O₂-binding to Tyr(43)B10 is coupled with heme distortion, interaction between Lys(64)E6 and the heme propionate, and interaction between Ser(68)E10 and Tyr(43)B10 through a distal water molecule, not present in the *BpeGReg-Gb** aquo-met form. Thus our data support the proposed mechanism that differences in ligation state at the distal side is potentially propagated through interactions with residues on the E helix, allowing for signaling to the DGC output domain. Furthermore, a second crystal form of ferric *BpeGReg-Gb** reveals the presence of two possible dimerization modes, both based on the G-H helical bundle. The first dimerization mode is that typically found in GCSs, the second differs by a rotation of 60° between monomers and is stabilized/forced by the presence of an extra heme molecule, probably due to a somewhat higher heme availability in solution at the more alkaline crystallization condition used (see Material and Methods, condition 2), covalently linking two His residues (His155) at the end of the H helices (the region which is linked to the middle domain of the full-length protein). Although this dimerization mode could be classified as a crystallization artifact, it clearly demonstrates that the G-H surface of a monomer is intrinsically characterized by high plasticity, being able to face, fit and bind its counterpart in more than one way. The different dimerization mode is also associated with a different distal site organization, with Tyr(43)B10 swinging in and out the distal site. Thus, a transmission mechanism through a partial rotation at the G-H interface is conceivable, whereby a different relative position of the H-helices upon ligand binding would directly affect the following middle domain and/or affect the global oligomerization state of the full-length protein (dimer with low diguanylate cyclase activity vs tetramer with high activity) (51).

Our *in vitro* data on DGC activity in *AvGReg* demonstrate that O₂-binding to *A. vinelandii* GCS triggers c-di-GMP biosynthesis, as described for *B. pertussis* GCS (20,33,51,70). In bacteria, C-di-GMP is an essential second messenger involved, *in vivo*, in the regulation (translational and post-translation) of motility, exo-polysaccharide production and biofilm

formation (26,34,49,52). Thus O₂ binding to GCS as *A. vinelandii* and *B. pertussis*, increases c-di-GMP production and activates biofilm formation.

Innovation

Biofilms are considered an important medical and industrial issue and, consequently, GCS with DGC activity are becoming a class of enzymes of increasing scientific interest. This paper extends the knowledge on the GCS proteins. It provides a comprehensive biochemical and structural characterization of *A. vinelandii* and *B. pertussis* O₂ sensors involved in the control of biofilm formation and biofilm maintenance through production of the c-di-GMP second messenger.

Materials and Methods

Cloning, expression, mutagenesis and protein purification

Full-length AvGReg (472 residues) and its N-terminal globin domain AvGReg-Gb (residues 1-170) were amplified by PCR, and cloned into the pBAD-a vector as previously described (14,47,64). In addition, for the AvGRegYB10F variant, Tyr(44)B10 was mutated into Phe using the QuickChangeTM site-directed mutagenesis method (Stratagene) (15). All were expressed as N-terminal His-tagged proteins in *E. coli* TOP10 cells (Invitrogen) (14,47) and purified from the soluble fraction using affinity chromatography. This procedure is very different from the one used to obtain [†]AvGReg in (64). In that case, the procedure involved the purification of the expressed, denatured proteins from inclusion bodies, with a subsequent *in vitro* folding in the presence of hemin. This approach deviates significantly from the here presented method based on *in-vivo* folding of the proteins in *E. coli* followed by affinity purification.

Full-length BpeGReg (475 residues) and its N-terminal globin domain (BpeGReg-Gb) (residues 1-169) were amplified by PCR and cloned into the pET23-a vector using NdeI and XhoI restriction sites. The C-terminal His-tagged fusion proteins were expressed in *E. coli* BL21(DE3)pLysS (Invitrogen) as done for the AvGReg proteins (14,47). To prevent aggregation during the crystallization process, four out of six cysteine residues present in the globin domain (Cys16, Cys45, Cys114, Cys154) were mutated into Ser using the QuickChangeTM site-directed mutagenesis method (Stratagene) (15). The selection for the Cys residue to be mutated was done based on the *in silico* modelling of BpeGReg-Gb obtained by using the I-TASSER server (72). The mutated proteins are further termed and

*BpeGReg** (full length molecule) and *BpeGReg-Gb** (globin domain). The *AvGReg* proteins were kept in 50mM Tris-HCl pH 7.5, 50mM NaCl, 10mM MgCl₂ and 5% glycerol, whereas the *BpeGReg* proteins were kept in 20mM Tris-HCl pH 8, 50mM NaCl and 40% glycerol. Both the globin domains were kept in 50 mM Tris-HCl pH 8.5, 10 mM NaCl and 0.5 mM EDTA.

UV/Visible absorption spectroscopy

The optical absorption measurements were obtained by using a Varian Cary 5E UV-Vis-NIR spectrometer. The spectra were recorded from 350 nm to 750 nm at room temperature. The ferrous O₂-ligated forms were measured, without additional treatment (as-purified), soon after protein purification, while the unligated form was obtained by adding 1% v/v sodium dithionite saturated solution to the sample, after N₂ bubbling.

Resonance Raman spectroscopy

The resonance Raman (RR) spectra were measured on a Dilor XY-800 Raman spectrometer in low-dispersion mode, associated to a liquid N₂-cooled CCD detector (slit width = 200 μ m), with a Kr⁺ laser operating at 413.1 nm as the excitation source (Spectra-Physics BeamLok 2060). The applied laser power was 10 mW (*BpeGReg* proteins) and 15 mW (*AvGReg* variants). The samples had a final concentration of 40 μ M, and were magnetically stirred at 500 rpm to avoid local heating and photochemical decomposition. Six spectra were recorded with 120-180 s integration time, depending on the protein sample. To remove spikes due to cosmic rays, the highest and lowest data points for each frequency value were removed and averaged over the remaining values with an in-house written program.

Ligand binding kinetics and data analysis

Laser flash photolysis experiments were performed to measure the CO and O₂ binding kinetics at 20 °C using a laser photolysis system (Edinburgh Instruments LP920, UK) equipped with a frequency-doubled, Q-switched Nd:YAG laser (Quanta-Ray, Spectra Physics). A laser flash of 532 nm was used.

The carbon monoxide (CO)-ferrous Hb complexes were prepared in sealed 4 × 10 mm quartz cuvettes with 1 ml of 100 mM potassium phosphate buffer (pH 7.0) containing 1 mM EDTA. The buffer was equilibrated with mixtures of CO and N₂ in different ratios to obtain CO concentrations of 50–800 μ M by using a gas mixer (HighTech System;

Bronkhorst, The Netherlands). Saturated sodium dithionite solution (10 μ l) was added and the protein was injected to a final concentration of ~ 4 μ M. Formation of the CO–ferrous Hb complex was verified by UV/visible absorption spectroscopy. Recombination of the photo-dissociated CO ligand was monitored at 418 nm (*BpeGReg*) or 421 nm (*AvGReg*).

O₂/CO competition studies were performed with the ferrous oxygenated (as-purified) form of the GCS. Sealed cuvettes containing 100 mM phosphate buffer pH 7.0 were flushed with O₂/CO mixtures (O₂ concentrations between 250 and 812.5 μ M, and CO concentrations between 350 and 800 μ M). The protein was added to the experimental cuvettes immediately prior to the photolysis experiment. The CO/O₂ displacement was followed at 418 nm and 436 nm for *BpeGReg* and at 421 nm and 436 nm for *AvGReg*.

The data obtained were analyzed with MATLAB® (The MathWorks, Inc., Natick, Massachusetts, USA) and fitted with Origin (OriginLab, Northampton, Massachusetts, USA). The time courses for CO rebinding followed a mono exponential decay and were fitted to the minimum reaction mechanism (scheme 1) with equations as described elsewhere (42,64).

The O₂/CO competition time courses fitted with a two-exponential process (Scheme 2, (42)), valid also for the globin domain alone:

The values of k'_{O_2} , k_{O_2} , and k'_{CO} were obtained according to the equations:

$$k_f = k'_{O_2}[O_2] + k'_{CO}[CO] + k_{O_2} \quad (\text{Equation 1})$$

$$k_s = \frac{k_{O_2}}{1 + \frac{k'_{O_2}[O_2]}{k'_{CO}[CO]}} \quad (\text{Equation 2})$$

where k_f is the fast observed reaction constant k_{obs} , and k_s is the slow k_{obs} at a given ligand concentration.

The slower O_2 dissociation rate constant was determined with a ligand replacement method using stopped flow, as already described (41). Experiments were performed at 20 °C in triplicates on an Applied Photophysics SX20 stopped-flow spectrometer apparatus equipped with the Pro-Data™ software suite. After measurements, the raw data were further analyzed with Origin (OriginLab, Northampton, Massachusetts, USA). The oxygenated protein solution was rapidly mixed with an O_2/CO mixture (the final protein concentration after mixing was 2.5 μM) in 100 μM potassium phosphate buffer pH 7.5, 1 mM EDTA.

Diguanylate cyclase assay

A HPLC-based DGC assay was adapted from (54) and performed in triplicate to quantify c-di-GMP synthesis by AvGReg. Shortly, 10 μM of enzyme was incubated at 37 °C with 20 to 65 μM GTP in 50 mM TRIS-HCl pH 7.5, 50 mM NaCl and 10 mM $MgCl_2$. Aliquots were taken at different times and the reaction was rapidly stopped with one-fourth volume of 0.5 M EDTA pH 8.0, which ensures repeatability in the measurement of more time points in a few seconds time frame, as required for initial rate determination of enzymatic processes. For deproteination, the stopped reaction mixture was heated for 5 min at 95 °C and centrifuged for 10 minutes at 11,300 x g. 20 μl of the supernatant was injected onto an Adsorbosphere Nucleotide-Nucleoside RP C18 HPLC column (Alltech, 250x4.6 mm) equipped with the same type guard column (Alltech/Grade, 7.5x4.6 mm). As mobile phase, 0.15 M NaH_2PO_4 and 40% acetonitrile was used. A relatively rapid linear gradient from 0% to 35% acetonitrile, for 10 minutes at 1 ml min⁻¹, was applied to separate GTP, c-di-GMP and pGpG, with which we could efficiently process the high number of samples produced. Known amounts of all three molecules were used for standardization.

Given the high sensitivity of AvGReg to product inhibition, low substrate concentrations were used. When the substrate concentration $[S] \ll K_m$, then $[S]$ is almost negligible and the Michaelis-Menten's equation becomes:

$$v_i = \frac{V_{max}[S]}{K_m}$$

Given that $V_{max} = k_{cat}[E]_0$, in our experimental conditions the enzyme specificity constant (k_{cat}/K_m) can be calculated from Michaelis-Menten plots.

Crystallization, structure determination, and refinement

Crystallization of AvGReg-Gb and *Bpe*GReg-Gb* was achieved using the sitting drop vapour diffusion method. AvGReg-Gb crystals were obtained by equilibrating at 4 °C the protein solution (30 mg ml⁻¹) against 33% PEG 6000 and 10 mM Na-citrate. The crystals diffracted up to 2.83 Å resolution, using synchrotron radiation (Elettra - Sincrotrone Trieste S.C.p.A, Trieste, Italy; XRD1 beamline). They belong to the monoclinic *P*2₁ space group and two AvGReg-Gb molecules per asymmetric unit (estimated solvent content 33%) (Table 4). *Bpe*GReg-Gb* crystals grew at 4 °C by using two different ionic and pH conditions: 1.6 M magnesium sulphate and 0.1 M MES pH 6.5 (condition 1: *Bpe*GReg-Gb*) or 0.8 - 1 M ammonium sulphate and 0.1 M TRIS-HCl pH 6.0 - 9.0 (condition 2: *Bpe*GReg-Gb*-2). The crystals grown under condition 1 and 2 diffracted up to 3.20 Å and 1.55 Å resolution, respectively, using synchrotron radiation (at SOLEIL and ESRF facilities, France). Both crystal forms belong to the C2 space group, but with different cell parameters, and contain two protein molecules in the asymmetric unit (estimated solvent content 48.25 % for *Bpe*GReg-Gb*, and 34.69 % for *Bpe*GReg-Gb*-2) (Table 4). MOSFLM (31), SCALA (18), and the CCP4 suite programs (71) were used for reducing, scaling and analysing all the collected data.

The *Bpe*GReg-Gb*-2 structure was solved with a combination of single wavelength anomalous dispersion (based on the heme-Fe atom anomalous signal) and molecular replacement. Few regions of the structure were built based on the SAD data. This partial model was used to determine the remaining phases with Phaser molecular replacement program (35). The molecular model was checked manually with COOT (17) and refined with REFMAC5 (37,38) to the maximum resolution (Table 4). The *Bpe*GReg-Gb*-2 refined structure was used as starting model (as a monomer) to solve the *Bpe*GReg-Gb* and the AvGReg-Gb dimeric structures with Phaser (35). The resulting structures were remodeled by using COOT (17) and refined with REFMAC5 (37,38) (Table 4). Their stereo chemical quality was assessed with MolProbity (9) and the quaternary assemblies were identified

with PISA (30). Finally, the atomic coordinates and the structure factors have been deposited in the Protein Data Bank (www.rcsb.org) with entry codes 4UII (AvGReg-Gb), 6I2Z (*BpeGReg-Gb**), and 4UIQ (*BpeGReg-Gb*-2*).

Acknowledgements

This work was supported by the Fund of Scientific Research – Flanders (FWO) grant no. G.0247.09N and supported by the University of Antwerp through the GOA biofilm project 25624 (GOA BOF UA 2011-2014) and the GOA-BOF project 28312. F.G. is a PhD fellow of the Fund of Scientific Research – Flanders (FWO). A.D.S. was funded by a PhD grant of the Innovation by Science and Technology (121339) (IWT, Belgium). The authors thank Mirosław Tarnawski and Thomas Barends for making the *EcDosC* model (full-length) available. The authors have no conflict of interest to declare.

Abbreviations:

AfGCHK = globin-coupled histidine kinase from *Anaeromyxobacter* sp. Fw109-5

AvGReg = globin-coupled regulator from *Azotobacter vinelandii*

AvGReg-Gb = AvGReg globin domain

AvGRegYB10F = AvGReg with Tyr(44) mutated to Phe

AvGReg178 = recombinant and reconstructed (heme + apoprotein) globin domain

BjFixL = *Bradyrhizobium japonicum* nitrogen fixation gene expression regulator

BsHemAT = *Bacillus subtilis* heme-based aerotaxis transducer

BpeGReg = globin-coupled sensor from *Bordetella pertussis*

BpeGReg* = BpeGReg with cysteines (Cys16, 45, 114, 154) mutated to serines

BpeGReg-Gb = BpeGReg globin domain

BpeGReg-Gb* = BpeGRegGb with cysteines (Cys16, 45, 114, 154) mutated to serines

c-di-GMP, cyclic-di-(3',5')-GMP

DGC = diguanylate cyclase

EcDosC = *E. coli* globin-coupled sensor with DGC activity

EcDosC-heme = isolated globin domain of the *E. coli* globin-coupled sensor

GCS = globin-coupled sensor

GsGCS¹⁶² = sensor domain from the *Geobacter sulfurreducens* globin-coupled sensor

PDE = phosphodiesterase

RmFixL* = soluble truncated domain of the *Rhizobium meliloti* nitrogen fixation gene expression regulator

Rmsd = root mean squared deviation

RR, Resonance Raman spectroscopy

RrCooA = *Rhodospirillum rubrum* carbon monoxide oxidation activator; sGC, soluble guanylyl cyclase

SwMb = sperm whale myoglobin

Antioxidants and Redox Signaling

Structural and functional characterization of the globin-coupled sensors of *Azotobacter vinelandii* and *Bordetella pertussis* (DOI: 10.1089/ars.2018.7690)

Additionally allowed	11.9	7.7	1.3
Disallowed regions	0.0	0.0	0.0

^a Highest resolution shell parameters are in parentheses

^b R-merge = $\sum_h \sum_i |I_{hi} - \langle I_h \rangle| / \sum_h \sum_i I_{hi}$

^c R-factor = $\sum_h ||F_{obs}| - |F_{calc}|| / \sum_h |F_{obs}|$, with F_{obs} being the observed and F_{calc} the calculated structure factor amplitudes

Figure legends

Figure 1. Resonance Raman spectra of AvGReg.

RR spectra of AvGReg (a,b) and AvGReg-Gb (c,d) in the low-frequency region (A) and high-frequency region (B) and RR spectra of BpeGReg (a,b) and BpeGReg-Gb (c,d) in the low-frequency region (C) and high-frequency region (D). Traces (a,c) show the RR spectra of the proteins as purified (oxygenated Fe(II) state), traces (b,d) show the RR spectra of the dithionite-reduced proteins (ferrous state). Wavenumbers marked with asterisk indicate reminiscent contributions of dithionite as described in (8).

Figure 2. Ligand binding kinetics curves for AvGReg.

(A) Experimental curves of the CO-rebinding to AvGReg (black: 200 μM CO, red: 400 μM CO, green: 600 μM CO, blue: 800 μM CO). The dependence of the pseudo-first order constants of CO binding (k_{obsCO}) to AvGReg on the relative ligand concentration is reported in the inset. (B) Stopped-flow O₂/CO replacement experimental curves of AvGReg (black: 50% CO - 50% O₂, red: 60% CO - 40% O₂, green: 70% CO - 30% O₂, blue: 80% CO - 20% O₂). The *fast* and the *slow* replacement phases are detectable for all the gas ratios used. (C) Dependence of the apparent k_f constants of O₂ binding to AvGReg on the relative ligand concentration. (D) Dependence of the apparent k_s constants of CO binding to AvGReg on the relative ligand concentration. Experimental values are reported with open circles, while the theoretical ligand-binding mechanism is represented with a straight line.

Figure 3. Ligand binding kinetics curves for *BpeGReg*.

(A) Experimental CO-rebinding decays to *BpeGReg* (black: 200 μM CO, magenta: 400 μM CO, green: 600 μM CO, blue: 800 μM CO) with the corresponding fitting curves (in red color). The dependence of the second order constants of CO binding (k_{obsCO}) to *BpeGReg* on the relative ligand concentration is reported in the inset. Experimentally obtained values are indicated with closed (fast rebinding) and open (slow rebinding) circles, the theoretical fitting lines are reported in red. (B) Dependence of the apparent k_f constants of O_2 binding to *BpeGReg* on the relative ligand concentration. (C) Dependence of the apparent k_s constants of CO binding to *BpeGReg* on the relative ligands concentration ratio. Experimental values are reported with open circles, while the theoretical ligand-binding mechanism is represented with red lines.

Figure 4. Enzymatic characteristics of the DGC activity of AvGReg.

(A) Reaction rate. **(B)** Summary of 3 independent measurements.

Figure 5. Tertiary structures.

Ribbon representation of the tertiary structure of (A) AvGReg-Gb (green) and (B) BpeGReg-Gb* (cyan). Helices are labelled accordingly with the globin fold nomenclature. The extra-turn of the F helix of AvGReg-Gb is shown in magenta. Proximal His residues and Fe^{3+} -ligated water molecules are indicated. (C) α -trace overlay of the AvGReg-Gb A (green) and BpeGReg-Gb* (cyan). Regions displaying the main structural differences are highlighted.

Figure 6. Quaternary structures.

Top view of (A) the AvGReg-Gb dimer, and (B) the BpeGReg-Gb* dimer, with the two subunits interacting mainly through the G- and H-helices (helical bundle), shown as ribbon models. The heme groups are shown in red. (C) Dimeric arrangement of BpeGReg-Gb*-2. The dimeric interface involves the G- and H-helices as in the BpeGReg-Gb* dimer, but the subunits are oriented differently. (D) Relative orientation of the B subunits of BpeGReg-Gb* (blue) and BpeGReg-Gb*-2 (pink), after superimposing the two A chains (omitted in the picture for clarity). The rotation of 60° is highlighted, taking the position of the G helices as reference. (E, F) The heme group at the top of the BpeGReg-Gb*-2 dimer is modelled in two conformations (green and yellow) with 0.5 occupancy each, with the Fe-atom hexacoordinated to the His155 side chain of the two subunits of the dimer.

Figure 7. Proximal and distal sites.

The figure shows the main residues building the heme proximal and distal sites for (A) AvGReg-Gb (A chain), (B) *BpeGReg-Gb** (A chain), (C,D) *BpeGReg-Gb*-2* (A and B chains). The AvGReg-Gb and *BpeGReg-Gb** distal sites host a water molecule (gray) coordinated to the heme-Fe³⁺. In *BpeGReg-Gb*-2* a coordination with Tyr43 is present in the A chain, while an imidazole molecule is bound in the B chain.

Supplementary legends

Figure S1. Resonance Raman spectra of *BpeGReg and *BpeGReg-Gb**.**

RR spectra of *BpeGReg** (a,b) and *BpeGReg-Gb** (c,d) in the low-frequency region (A) and high-frequency region (B). Traces (a,c) show the RR spectra of the proteins as purified (oxygenated Fe(II) state), traces (b,d) show the RR spectra of the dithionite-reduced proteins (ferrous state). Wavenumbers marked with asterisk indicate reminiscent contributions of dithionite as described in (8). These signals hamper the analysis of the low-frequency region of the RR spectrum of *BpeGReg-Gb**.

Figure S2. Detailed Resonance Raman spectrum of O₂-AvGReg.

The figure zooms in on the region in which the Fe-O₂ modes are visible.

Figure S3. UV/Vis absorption (A) and Resonance Raman (B,C) spectra of ferric AvGReg.

AvGReg was oxidized by addition of potassium ferricyanide. **(A)** The Soret and Q-bands confirm the oxidation to a ferric low-spin form. However, the presence of a peak at 646 nm indicates that also partial degradation has taken place (formation of hemochrome derivatives, like biliverdin). **(B,C)** The RR spectra are similar to those observed previously for the *in-vivo* refolded $^{+}$ AvGReg (64). RR peaks confirm the assignment from (prominent peaks at $\nu_3=1505\text{ cm}^{-1}$ confirms the low-spin (hexa-coordination of the heme)). Additionally, the observation of small peaks in the area of $545\text{--}565\text{ cm}^{-1}$ indicate that some of the proteins are still in the oxygenated ferrous form. Interestingly, the 573 cm^{-1} peak has disappeared indicating that this open configuration of the heme group oxidizes the easiest.

Figure S4. Ligand binding kinetics curves for AvGRegYB10F.

(A) Experimental curves of the CO-rebinding to AvGRegYB10F (black: 200 μM CO, red: 400 μM CO, green: 500 μM CO, blue: 600 μM CO, cyan: 800 μM CO). The dependence of the pseudo-first order constants of CO binding ($k_{obs,CO}$) to AvGReg YB10F on the relative ligand concentration is reported in the inset. (B) Stopped-flow O₂/CO replacement experimental curves of AvGRegYB10F (black: 90% CO - 10% O₂, red: 80% CO - 20% O₂, green: 60% CO - 40% O₂, blue: 40% CO - 60% O₂, cyan: 20% CO - 80% O₂). The *fast* and the *slow* replacement phases are detectable for all the gas ratios used. (C) Dependence of the apparent k_f constants of O₂ binding to AvGRegYB10F on the relative ligand concentration. (D) Dependence of the apparent k_s constants of CO binding to AvGRegYB10F on the relative ligand concentration. Experimental values are reported with open circles, while the theoretical ligand-binding mechanism is represented with a straight line.
