# Strategic Multi-Echelon and Cross-Modal CO<sub>2</sub> Emissions Calculation in Parcel Distribution Networks. A First Step Toward a Common Language

## Abstract

Sustainability in distribution networks is currently the focus of study at institutional, academic, and commercial levels. Reducing greenhouse gas emissions is on all the programmatic agendas, and the goals are clear for years toward carbon neutrality. As one of the main polluting sectors and growing trends with e-commerce, transport must align its efforts to contribute to the cause. In this paper, a strategic model is proposed for the calculation of CO<sub>2</sub> emissions in the distribution of parcels. Novel in this research is that it integrates both line-haul transport and last-mile distribution at a strategic level and includes key elements such as time windows and population density in the calculation. Through an applied case in the parcel distribution in Belgium, the calculation of CO<sub>2</sub> emissions with the proposed model is illustrated. The model is enhanced by analysing the time windows effect and the electrification of the last-mile fleet. The results of CO<sub>2</sub> emissions in parcel distribution in Belgium show that it is possible to reduce emissions not only through the electrification of the fleet but also with an efficient distribution network. The effect of the network structure will be more evident with international shipments that include more polluting modes of transport. However, the results for Belgium show that the last mile is currently the most polluting segment. The proposed model could further be complemented by including reverse logistics, in-house calculation, and packaging emissions.

**Keywords:** CO<sub>2</sub> emissions, calculation, integrated modelling, supply network, parcel distribution

## 1 Introduction

One of the significant concerns today is climate change and global warming. These concerns are reflected in global and regional agreements for reducing pollutant emissions and setting sustainable development objectives by the United Nations. The European Commission has defined the main objective of the Green Deal as the reduction of greenhouse gas emissions by 55% compared to 1990 levels by 2030 [1]. Specifically, for commercial vehicles such as vans, the reduction of CO<sub>2</sub> emissions should be 50% by 2030, and for 2030 the goal is zero emissions for new cars. Transportation is the most significant source of greenhouse gas emissions in the United States (27%) [2], and the second worldwide (24%), only surpassed by electricity and heat producers (42%) [3].

Road transport had the highest emissions within the transport sector in 2018 worldwide (74.5%), corresponding to 45.1% to passenger transport and 29.4% to freight [4]. Aviation contributed 11.6% of total CO<sub>2</sub> transport-related emissions, of which 19% come from freight; shipping counted for 10.6%. With these figures, it can be established that freight transport, in all modes contributed 42.2% to total transport CO<sub>2</sub> emissions in 2018. Since 2019/2020, these values have changed significantly because of the Covid-19 pandemic, especially in the passenger transport segment. According to the European

1 Parliament [5], with data from the European Environmental Agency, in 2019, only 11% and 1.3% of  
2 the emissions generated by road transport correspond to light-duty trucks and motorcycles, respectively.  
3 These vehicles are used in last-mile distribution, which shows that the bulk of the emissions is generated  
4 in line-haul transportation.

5 Measuring greenhouse gas emissions is a step toward achieving the emissions reduction goals. But at  
6 this point a question arises, do we speak the same language when calculating emissions? Although some  
7 stakeholders are already measuring the CO<sub>2</sub> emissions generated in transport, as is the case of airlines  
8 [6], a standard measurement throughout the whole supply network is essential. In this case, it is not  
9 enough to add separate measurements; integrated models are needed. The need for a standard emissions  
10 calculation also exists in the distribution of parcels. The global growth of retail Business-to-Customers  
11 (B2C) e-commerce has been such that by 2020 it already represented 18% of total sales. It is expected  
12 to grow at least 1% in the following years. A comprehensive calculation of CO<sub>2</sub> emissions in the parcel  
13 supply network must integrate both the last-mile and the line-haul transportation.

14 The objective of this paper is to propose a strategic model for the calculation of CO<sub>2</sub> emissions in parcel  
15 distribution networks. The strategic component contemplates integrating the line-haul and last-mile  
16 transport in a multi-echelon network and including all modes of transport. In order to take the modelling  
17 of the last-mile distribution from an operational level (classical Vehicle Routing Problem – VRP) to a  
18 strategic level, theoretical estimations of the route length are used. The paper is structured as follows;  
19 section 2 shows the literature overview and the bases for calculating CO<sub>2</sub> emissions in transport. Section  
20 3 develops the description of the problem and the definition of the model. An application of the CO<sub>2</sub>  
21 emissions calculation in the parcel distribution network in Belgium is presented in section 4. Finally, in  
22 section 5, the practical implications and conclusions are presented.

## 23 **2 Transport CO<sub>2</sub> emissions: Literature overview, approaches, and calculators**

24 Searches in databases such as SCOPUS show that the literature on calculating CO<sub>2</sub> emissions in  
25 transport, using terms such as last-mile, supply chain, or network, has grown recently due to the  
26 sustainability boom. The CO<sub>2</sub> emissions as a decision variable have been used in the design of supply  
27 networks. Multi-objective optimisation minimises costs and CO<sub>2</sub> emissions [7] or selects an adequate  
28 transport mode [8]. Also, as a criterion for selecting suppliers with lower CO<sub>2</sub> emissions or higher green  
29 factors [9]. The base formulation is maintained using the weight of the load, the vehicle's capacity, the  
30 distance travelled, and the emission rate (emission factor) for loaded and empty vehicles [10].

31 In biomass supply chains, CO<sub>2</sub>e emissions (CO<sub>2</sub>e – equivalents is the conversion of all greenhouse gas  
32 emissions to CO<sub>2</sub> emissions) are part of the environmental assessment of the transport of raw materials  
33 [11]. In addition to the transportation of biomass, the CO<sub>2</sub> emissions from cultivating and harvesting oil  
34 palm [12] or sugar cane [13] are also contemplated in the biomass supply chain. More comprehensive

1 models such as life cycle analysis – LCA complemented with geographic and simulation analyses also  
2 use measurements of CO<sub>2</sub> emissions in biomass production.

3 The calculation of CO<sub>2</sub> emissions in supply chains of consumer goods has also contributed to the  
4 development of measurement methodologies. Multimodal approaches, including road and maritime  
5 transport, still use distance travelled averages instead of the actual network [14]. However, the  
6 methodological framework model for calculating emissions proposed by Mubarak & Zainal [14] does  
7 take into account the emissions from the transshipment centres. This is a differentiator in emission  
8 calculation models since it includes variables such as packaging, handling, and refrigeration energy.  
9 This methodology has also been used to compare logistic emissions in some Asian countries, as the  
10 authors argue that standard methods do not apply in these regions [15]. More specifically, in the last-  
11 mile distribution, Edwards et al. [16] performed a comparative analysis in terms of CO<sub>2</sub> emissions of  
12 conventional and online retailing. The authors showed that the CO<sub>2</sub> emission per item delivered using  
13 a van that drops 120 deliveries on a 50-mile route is around 181g/drop.

14 One direct measure for reducing CO<sub>2</sub> emissions in road transport is the electrification of vehicles. Since  
15 Tank-To-Wheel CO<sub>2</sub> emissions from electric vehicles are nominally zero, electric light commercial  
16 vehicles are the best for urban distribution [17]. Woody et al. [18] show the counterpart of electrification  
17 with an analysis of the trade-off between minimising costs and minimising GHG emissions in  
18 recharging electric vehicles. Recharging strategies at certain hours of the day show both economic and  
19 environmental benefits in this regard.

20 Even though bibliographical production is growing, most of the methodologies for calculating CO<sub>2</sub> and  
21 CO<sub>2</sub>e emissions do not come from the scientific literature. Davydenko et al. [19], [20] and Wild [21]  
22 present a good account of current standards and methods for CO<sub>2</sub> and CO<sub>2</sub>e emissions measuring and  
23 reporting. Elements from the regulatory point of view or institutional programs can be consulted in  
24 those works. Methodological approaches and key variables such as the emission factors in the emissions  
25 calculation will be described below.

26 The EN16258 standard establishes a 3-step methodology, where the transport service is first divided  
27 into individual sections or legs [22]. Then the calculation of greenhouse gas emission is made from the  
28 energy consumption, to add later the results of all the legs of the transport service [23]. Similarly,  
29 Mckinnon & Piecyk [24] proposed a 5-step methodology for measuring and reporting emissions, 1)  
30 define the objective, 2) select the calculation approach and system limits, 3) collect data and emission  
31 factors, 4) calculate, and 5) verify and report. The Greenhouse Gas Protocol – GHG [25] sets the  
32 emission measurements in three scopes, direct emissions (scope 1), indirect emissions from electricity  
33 (scope 2), and supply chain emissions (scope 3). However, this protocol is seen from the corporate  
34 level. For this reason, emissions due to transportation from suppliers are considered in scope 3.

1 According to the Green Logistics project executed by the Fraunhofer Institute, there are three emission  
2 calculation approaches consumption-based approach, distance-based approach (or activity), and key  
3 figure-based approach [26]. The approaches are related to the scopes proposed by the GHG protocol,  
4 scope 1 emissions are usually calculated with the consumption-based approach. For emissions in scope  
5 3, an activity-based calculation is more appropriate. The approach based on key figures seeks to  
6 aggregate the calculation of emissions from corporate figures and averages.

7 A broader methodological framework is proposed by the Smart Freight Centre [27] for the calculation  
8 of logistical emissions. The framework is based on the GHG protocol and contemplates three steps,  
9 from defining boundaries and objectives to calculating emissions in the different scopes. The  
10 distribution network view is contemplated in the Lean & Green program in the Netherlands, where  
11 optimisation in transportation planning is established as a measure to reduce emissions [28]. The  
12 program proposes that better planning of the tactical/operative operations in the distribution leads to  
13 eliminating unnecessary trips and consequently reducing emissions and costs.

14 Regarding the emission factors, the CE Delft [29] presents a wide range of Well-To-Wheel (WTW)  
15 emission factors for all modes of transport (except air). According to this study, for road transport, large  
16 vans, trucks, and semitrailer trucks have emission factors of 1153, 259, and 82 g/tkm, respectively.  
17 Likewise, in 2019 the French Ministry for the Ecological and Inclusive Transition published a  
18 methodological guide on greenhouse gas information for transport services [30]. This guide shows a  
19 complete list of energy sources with their respective emission factors for the operation and upstream  
20 phases. The official software of the European Commission for calculating energy consumption is the  
21 Vehicle Energy Consumption Tool – VECTO [31]. With this tool, the energy consumption of heavy-  
22 duty vehicles can be simulated to estimate the emission factors. Some results of the simulation with  
23 VECTO show that the emission factors for delivery vans and rigid and trailer trucks are 113.07, 275.2,  
24 and 61.2 g/tkm, respectively. The van emissions factor shows significant discrepancies between the  
25 values simulated by VECTO and those reported by CE Delft.

26 EcoTransIT World is an industry-driven platform for calculating the carbon footprint of freight  
27 transport [32]. The methodology used by EcoTransIT is in line with EN16258 standards and uses cargo  
28 type parameters for all modes of transport. It is worth highlighting the use of the resistance factor,  
29 which, although the tool does not contemplate routing, allows smaller vehicles to enter urban roads if  
30 comparable to taking longer routes by highways. Another tool is BigMile, a carbon analytics service  
31 that provides insights on the carbon footprint related to transportation. This service analyses shipments,  
32 customers, subcontractors, periods, and regions [33]. There are also tools for calculating emissions  
33 specialised in a single mode of transport. Perhaps the most comprehensive emissions calculator is  
34 CarbonCare, which integrates all transport modes and storage and cold chain emissions [34]. Based on

1 the EN16258 standard, Carbon Care calculates Great Circle Distances and emissions segment by  
2 segment.

3 In the postal and parcels sector, the UPU [35] has launched the Online Solution for Carbon Analysis  
4 and Reporting – OSCAR tool for calculating, reporting, and mitigating greenhouse gas emissions. Oscar  
5 is built based on the Greenhouse Gas Protocol methodology, which calculates emissions at the corporate  
6 level in 3 scopes [25]. Similar to the Smart Freight Centre methodological framework. Likewise, private  
7 initiatives such as the DHL [36] emissions calculator allow estimating the emissions of a shipment. This  
8 tool considers shipment legs with different modes of transport between two points.

9 In conclusion to this section, the unanimous call for a globally standardised calculation of CO<sub>2</sub>  
10 emissions is highlighted. Institutional and private initiatives have proposed standards for measuring  
11 CO<sub>2</sub> emissions that should be adopted in an integrated methodology. No CO<sub>2</sub> emissions calculator or  
12 methodologies simultaneously focus on last-mile deliveries and line-haul transportation. Integration of  
13 last-mile with network calculation in a strategic sense is the added value of this research. Wild [21]  
14 concludes that a global emission standard should be based on five aspects: simplicity, accuracy,  
15 flexibility, feasibility, and transparency.

### 16 **3 Methods**

#### 17 3.1 Problem description

18 The calculation of CO<sub>2</sub> emissions in the parcel distribution network is not only the last-mile distribution  
19 but also all the other levels upstream, as shown in Figure 1. Depending on each parcel player, there can  
20 be as many levels as the network is complex. In this study, the emissions reporting is defined per unit  
21 of cargo i.e., one parcel. Unit allocation is standardised to TTW (tank-to-wheel) CO<sub>2</sub> grams per parcel.  
22 In addition to the network approach, the multimodal character in the parcel distribution has significant  
23 implications on CO<sub>2</sub> emissions. Each mode of transport has different fuel consumption and, therefore,  
24 different emission factors. Although the emission factor of each vehicle is defined based on fuel  
25 consumption, the integrated calculation has an activity-based approach, as proposed for scope 3  
26 emissions in the Greenhouse Gas Protocol [25].

27 Integrating the last-mile distribution in the calculation ex-ante of emissions (before the operation) is a  
28 challenge from a modelling and computational point of view since the classic vehicle routing is an NP-  
29 Hard problem [37] i.e., very complex to solve in polynomial time by a nondeterministic Turing machine.  
30 Thus, the strategic calculation of the distance for the last-mile distribution is proposed, theoretically  
31 estimating the length of the route. The needed distance to distribute n parcels in a delimited area is  
32 explained in the model formulation.

33 

1 3.2 Model formulation

2 Calculating CO<sub>2</sub> emissions generated during parcel distribution includes the last-mile distribution and  
 3 line-haul transport. The identification of segments or legs proposed in the EN16258 standard is used to  
 4 define the last-mile segment and the different legs in the line-haul transport. A general expression for  
 5 the total CO<sub>2</sub> emissions per parcel is defined as  $\epsilon_p$  in Equation (1), see Appendix A for the complete  
 6 list of parameters.

$$\epsilon_p = eLh_p + eLm_p \quad (1)$$

7 The emissions corresponding to line-haul and last-mile transport are represented as  $eLh_p$  and  $eLm_p$ ,  
 8 respectively. Equations (2) and (3) show the composition of each term.

$$eLh_p = \frac{(d_{i,j} + d_{j,k} + \dots + d_{l,m})\epsilon f_v p_{vol/we}}{v_{vol/we}^{cap}} \quad (2)$$

$$eLm_p = \widehat{D}_{lm} + \epsilon f_v \quad (3)$$

9 Where  $d$  represents the distance between two different nodes in the network. In multi-echelon networks,  
 10 there will be as many indices as different nodes are: Set of nodes  $S = \{i, j, k, \dots, l, m\}$ . There are four  
 11 types of distance metrics for line-haul transport [38]: “Great Circle Distance” (GCD), which calculates  
 12 the distance between two points on the earth's surface, “Actual Driven Distance” (ADD) measured by  
 13 the same vehicle, “Planned Distance” (PD) the route of the vehicle is optimised by the planning  
 14 software, and “Shortest Feasible Distance” (SFD) within a specific network. Davydenko et al. [38]  
 15 found that the GCD is the most appropriate for calculating the carbon footprint. In this formulation, the  
 16 GCD is ideal for modes of transportation such as air or maritime, while for road transportation, the PD  
 17 provides greater accuracy in ex-ante calculations.

18 The emission factor per vehicle type  $v$  is represented by  $\epsilon f_v$ . The parcel dimensions are entered as  
 19  $p_{vol/we}$  either in terms of volume ( $vol$ ) or weight ( $we$ ).  $v_{vol/we}^{cap}$  represents the vehicle capacity either  
 20 in terms of volume or weight.  $\widehat{D}_{lm}$  is defined as the estimated average last-mile route length.

21 3.2.1 Estimation of average last-mile route length  $\widehat{D}_{lm}$

22 Multiple studies have demonstrated the use of theoretical route length estimation for last-mile  
 23 distribution. A generalisation of the Traveler Salesman Problem (TSP) proposed by Beardwood et al.  
 24 [39] found that the distance needed to visit  $n$  points from a depot within its area of influence tends to  
 25 Equation (4). Where  $k$  is a constant based on the distance metric used and  $A$  is equal to the area of the  
 26 influence.

$$\lim_{n \rightarrow \infty} E[d_{TSP}(n, A)] = k\sqrt{nA} \quad (4)$$

1 Later, Daganzo [40] complemented this formulation, including the line-haul as  $2r \frac{n}{C}$  with  $r$  an average  
 2 distance from the depot to the delivery area and  $C$  as the capacity of the vehicle. Since the calculation  
 3 of CO<sub>2</sub> emissions is based on a multi-echelon distribution network (Figure 1), the line-haul distance is  
 4 calculated as separate legs as shown in Equation (2). Recently, this estimation has been implemented  
 5 in the calculation of transport costs for the last-mile distribution [41]–[43]. Different values for the  
 6 constant  $k$  have been proposed, Bergmann et al. [44] summarise some of them like  $k \approx 0.765$  for  
 7 Euclidian distances and  $k \approx 0.97$  when using Manhattan distances.

8 Equation (4) is enhanced with two coefficients that modify the number of stops in the distribution route,  
 9 namely the effect of time windows ( $w$ ) and the population density ( $ad$ ) in the delivery area. Previously,  
 10 improvements to this general formulation have also been proposed, as in the case of Cardenas et al.  
 11 [45], for the inclusion of failed deliveries in the calculation of costs. Gevaers et al. [46] showed the  
 12 relationship of these coefficients with the number of stops as  $\left[\frac{stops}{w}\right]$  and  $[stops * ad]$  for the time  
 13 windows and the population density, respectively. Thus, the estimation of the route length with these  
 14 coefficients is determined by Equation (5).

$$\hat{D}_{lm} = k \sqrt{\frac{(n * ad)A}{w}} \quad (5)$$

15 In order to get the amount of CO<sub>2</sub> emission generated by each parcel, it is necessary to understand the  
 16 participation of each parcel during the entire route. Consider any parcel on a delivery route, the two  
 17 extreme scenarios in which this parcel can be delivered are: being the first or the last. If the parcel is  
 18 the first, the distance the parcel travel in the last mile is nominally zero, in contrast to being the last,  
 19 where the parcel has travelled the entire route. In this way, it is easy to find that the average distance  
 20 that any parcel travels on the route is half of the route  $\frac{\hat{D}_{lm}}{2}$ .

21 Similarly, the contribution of each parcel to the total CO<sub>2</sub> emissions depends on the number of parcels  
 22 in the route following economies of scale. Assuming that each stop is a parcel delivered, the vehicle's  
 23 capacity determines the initial number of stops. Thus, if the vehicle travels at its maximum capacity,  
 24 the CO<sub>2</sub> emission charged to each parcel is less than if it travels with a single parcel. With this logic,  
 25 the average amount of CO<sub>2</sub> emissions charged to any parcel is calculated with the average vehicle  
 26 capacity or half of the stops, so it is equal to  $\frac{\varepsilon f_v}{2} = \frac{2 \varepsilon f_v}{n}$ . Equation (6) shows the calculation of CO<sub>2</sub>  
 27 emissions per parcel in the last mile.

$$\hat{D}_{lm} = \frac{k \sqrt{\frac{(n * ad)A}{w}}}{2} \frac{2 \varepsilon f_v}{n} = \frac{k \sqrt{\frac{(n * ad)A}{w}}}{n} \varepsilon f_v \quad (6)$$

1 According to the above, the extensive form of Equation (1) is presented in Equation (7).

$$\epsilon_p = \left[ \frac{(d_{i,j} + d_{j,k} + \dots + d_{l,m}) p_{vol/we}}{v_{vol/we}^{cap}} + \frac{k \sqrt{\frac{(n * ad)A}{w}}}{n} \right] \epsilon f_v \quad (7)$$

## 2 4 The Belgian parcel distribution case

3 In Europe, e-commerce has grown steadily recently. In the last five years, the percentage of people who  
 4 buy on the internet (e-shoppers) went from 65% in 2017 to an expected value of 76% in 2022 [47]. This  
 5 indicator is higher in Belgium, where e-shoppers are expected to grow to 80% by 2022. In addition, the  
 6 COVID-19 pandemic has impacted e-retail, expanding accessibility to non-food products [48] and  
 7 consequently increasing the demand for parcel transport. According to the Belgian Institute for Postal  
 8 Services and Telecommunications [49], the five leading parcel players (PP) hold more than 80% of the  
 9 market of the parcel and express mail in terms of volume, as shown in Figure 2. The parcel players in  
 10 the Belgian market have been classified into the following typology: National Postal Operators,  
 11 integrators, parcel carriers, and last-mile specialists [45].

12 Figure 2. Market share within the segment of the parcel and express mail in Belgium. Source: [49]

13 The calculation of the CO<sub>2</sub> emissions is carried out in two scenarios to see the implications of the  
 14 network. **Scenario 1:** The five leading parcel players (PP) have been considered, namely Bpost, DPD,  
 15 Post NL, UPS, and GLS. The distribution networks have been identified with information from different  
 16 sources, including the official sites of these PP. Henceforth, the operators will be referred to as PP1 to  
 17 PP5, since the objective of this paper is not to evaluate the performance of any of them but rather to  
 18 illustrate the calculation of CO<sub>2</sub> emission in an applied context. Although the warehouses/hubs network  
 19 structures are not mentioned, it is noted that out of the five PP, four have a three levels-echelon network  
 20 and one a four levels-echelon network. Results in this scenario are presented as the weighted average  
 21 of CO<sub>2</sub> emissions based on the market share of each PP.

22 **Scenario 2:** A sixth parcel player (PP6) is analysed to see the implications of a shorter distribution  
 23 network. The parcel distribution model of PP6 has as its core the location of depots on the outskirts of  
 24 cities. This configuration results in a 2-echelon distribution network, with each city's depot as the  
 25 intermediate node. Results in this scenario show the actual CO<sub>2</sub> emissions using the PP6 distribution  
 26 network.

### 27 4.1 Travelled distance

28 The planned distances between the network nodes that compose the line-haul are calculated using  
 29 *OpenStreetMap*. The entire model has been programmed in Python. The last-mile distance is calculated  
 30 with Equation (5). The number of base stops is assumed to be  $n = 70$ , considering the capacity of a van  
 31 in an 8-hour working day. As mentioned in the model formulation, the number of stops is affected by

1 time windows and population density. Table 1 show the values for these coefficients based on [46]. In  
 2 this analysis, a value of  $k \approx 0.97$  is assuming the calculation of Manhattan distances.

3 Table 1. Time window and population density coefficients for last-mile distribution. Taken from Gevaers et al. [46]

Window length	Coefficient $w$	Number of inhabitants per km <sup>2</sup>	Coefficient $ad$
1 hour	2.1	0 – 50	0.5
2 hours	1.8	51 – 200	0.93
3 hours	1.6	333 (average in Belgium)	1
4 hours	1.3	201 – 400	1.09
No time window	1	401 – 600	1.24
		601 – 800	1.31
		801 – 1000	1.35
		1001 – 1200	1.38
		1201 – 1500	1.39
		> 1500	1.41

#### 4 4.2 Vehicle fleet and emission factors

5 In the case of parcel distribution in Belgium, the predominant mode of transport is by land. According  
 6 to observations in the operation of the PP, some types of vehicles are assumed for different network  
 7 segments. Trailer trucks and rigid trucks are used for line-haul transport, while delivery vans are used  
 8 for last-mile distribution. Table 2 shows the characteristics of the vehicles used. The average payload  
 9 and emission factors have been simulated with the VECTO tool [31]. In Section 2, the emission factors  
 10 were expressed in g/tkm. A conversion of those factors is shown here using the average payload. The  
 11 reason for this conversion is to move from ton analysis to unit of cargo analysis, such as parcels. For  
 12 scenario 2, the PP6 case is used to assess the impact of fleet electrification for the last mile on total CO<sub>2</sub>  
 13 emissions. Electric vehicles have nominally zero CO<sub>2</sub> emissions TTW.

14 Table 2. Vehicle information and emission factors.

Vehicle type	Average Payload	Dimensions LxWxH	TTW CO <sub>2</sub> Emissions Factor
Trailer truck	13.482 Ton	13.6x2.45x3 m	825.0984 g/km
Rigid truck	2.355 Ton	7.2x2.4x2.35 m	648.096 g/km
Delivery van	1.3 Ton	4.1x1.8x1.75 m	147 g/km

#### 15 4.3 Results and discussion: CO<sub>2</sub> emissions per parcel in Belgium

16 Initially, the results of the calculation of the CO<sub>2</sub> emissions without time windows are presented. For  
 17 each of the scenarios described above the emissions of two routes are calculated, from a national origin  
 18 in the city of Namur, Belgium (Wallonia region) and an international origin from Waalwijk in the  
 19 Netherlands. The distribution is illustrated in 8 cities where PP6 operates, comparable in both scenarios.  
 20 According to each PP, the distribution network includes different national, regional, and local hubs. The  
 21 assumed average parcel dimensions LxWxH are 30x30x25 cm. As the weight of the parcels is low, the  
 22 capacity of the vehicles is determined by the volume. Table 3 summarizes the results of the CO<sub>2</sub>  
 23 emissions calculation, detailing the emissions in the line-haul (LH) and in the last-mile (LM).

1

Table 3. Results of CO<sub>2</sub> emissions calculation [CO<sub>2</sub> g/parcel]

Destination/Origin	Scenario 1				Scenario 2			
	Namur		Waalwijk		Namur		Waalwijk	
	LH	LM	LH	LM	LH	LM	LH	LM
Antwerp	26	243	30	243	31	243	22	243
Brussel	23	216	27	216	22	216	36	216
Ghent	33	212	37	212	39	212	41	212
Hasselt	42	172	46	172	21	172	29	172
Leuven	28	127	32	127	17	127	31	127
Charleroi	37	172	41	172	10	172	50	172
Liege	42	141	46	141	19	141	41	141
Mechelen	68	137	72	137	23	137	29	137
<b>average</b>	37	178	41	178	23	178	35	178
<b>Global average</b>	215		219		200		212	

2

LH: Line-haul; LM: Last-mile

3 The CO<sub>2</sub> emissions per parcel per scenario for each of the eight selected cities from Namur, BE are  
 4 shown in Figure 3. The global average of CO<sub>2</sub> emissions in scenario 1 is 215 g/parcel and 200 g/parcel  
 5 in scenario 2. Interestingly, cities like Charleroi, relatively close to the Namur origin, do not necessarily  
 6 have the lowest emissions. This corresponds to the fact that line-haul transport considers the actual  
 7 distribution network of the PP, and many of them have their central hub in Brussels. In this way,  
 8 regardless of the geographical proximity between the origin and the destination, the parcel must follow  
 9 the route given by the PP. In large cities, the largest PP in scenario 1 already has a hub, so emissions  
 10 are lower compared to scenario 2. This is reversed in small cities, where the positioning of the depots  
 11 in scenario 2 allows a more efficient distribution. Distances travelled in both scenarios are shown in  
 12 Appendix B.

13

Figure 3. Average CO<sub>2</sub> emissions per parcel in 8 Belgian cities. Distribution from Namur, BE

14 In the international case with origin in Waalwijk, NE, the global average of CO<sub>2</sub> emissions is 219  
 15 g/parcel in scenario 1 and 212 g/parcel in scenario 2. The results by the city are presented in Figure 4.  
 16 Although the origin is international, the national distribution network is the same. That is, the parcels  
 17 must enter the national distribution network that each PP owns. This fact emphasises the importance of  
 18 the distribution network and implications for emissions beyond origin and destination. In both cases,  
 19 international and national, Leuven presents the lowest emissions. This situation responds to the  
 20 geographical location near Brussels, where all PP's distribution hubs converge. In general terms, the  
 21 results show that a shorter distribution network (PP6 in scenario 2) translates into a more efficient  
 22 operation and therefore generates lower CO<sub>2</sub> emissions.

23

Figure 4. Average CO<sub>2</sub> emissions per parcel in 8 Belgian cities. Distribution from Waalwijk, NE

24 To illustrate the effect of time windows on CO<sub>2</sub> emissions during the parcel distribution, Figure 5 shows  
 25 the emissions per parcel in the cities of Antwerp and Charleroi. It is evident that by implementing  
 26 narrower time windows, the CO<sub>2</sub> emissions increase. This is a pure last-mile effect. At tighter time  
 27 windows, fewer parcels can be delivered [46] since routes result in a ping pong effect. Not necessarily

1 because the distance travelled increases, but because economies of scale are lost in the capacity of the  
2 vehicles and the CO<sub>2</sub> emissions that are charged to each parcel increase. According to Equation (5), as  
3 the number of stops decreases due to the effect of the time windows, the estimated distance for the last  
4 mile is expected to decrease.

5 Figure 5. Average CO<sub>2</sub> emissions per parcel in 2 Belgian cities with different time windows. Distribution from Namur, BE  
6 The electrification of the last-mile distribution fleet reduces CO<sub>2</sub> emissions as expected (See Figure 6).  
7 However, total CO<sub>2</sub> emissions go from 200 g/parcel using conventional vans to 23 g/parcel with a 100%  
8 electric fleet. This shows that in the distribution of parcels in Belgium, more than 80% of the emissions  
9 are generated in the last mile.

10 Figure 6. Average CO<sub>2</sub> emissions per parcel with last-mile fleet electrification. Distribution from Namur, BE

## 11 **5 Conclusion**

12 The results of CO<sub>2</sub> emissions in parcel distribution in Belgium show that it is possible to reduce  
13 emissions not only through the electrification of the fleet but also with an efficient distribution network.  
14 The effect of the network structure will be more evident with international shipments that include more  
15 polluting modes of transport. However, the results for Belgium show that the last mile is currently the  
16 most polluting segment. Although the transport CO<sub>2</sub> emissions are the focus of attention, it cannot be  
17 ignored that other operations in the e-commerce supply chain are generating emissions. In 2020 the  
18 breakdown of estimated e-commerce greenhouse gas emissions mainly came from packaging level  
19 (45%), followed by return rates (25%); compared to traditional retail, where transportation is the most  
20 significant pollutant source (70%) [50]. These are elements that should be considered in a  
21 comprehensive CO<sub>2</sub> emissions calculation.

22 The existing methodologies support calculating CO<sub>2</sub> emissions and provide the guidelines according to  
23 the different approaches. Accepting the guidelines of the EN16258 standard regarding the calculation  
24 segmented by transport legs but using the same calculation methodology is fundamental. Adding the  
25 results of isolated calculations carried out by each operator is not the same. The integration of the last  
26 mile in transport emissions calculations is essential, and the strategic formulation allows estimating the  
27 distances of this segment without the need for classical routing algorithms. The formulation presented  
28 in this paper provides the flexibility and simplicity necessary to standardise emissions calculation.

29 The results of this study have practical implications for different stakeholders. First, for parcel  
30 distribution companies an additional opportunity to achieve green goals is the reconfiguration of their  
31 distribution networks. Not only does the electrification of the fleet have direct effects on the reduction  
32 of the level of emissions, but the redesign of the routes could generate a positive greening effect.  
33 Second, in terms of policy development, knowing that the last mile is the most polluting segment should  
34 indicate where the greatest efforts are needed. Even though the loss of economies of scale by using

1 smaller-capacity vehicles is an aggravation of the situation, the trend towards the use of cargo bikes or  
2 small electric vehicles is correct. Third, consumers must be aware that some of their consumption  
3 practices have a negative impact on emissions. This study shows that the shorter the time windows, the  
4 higher the emissions. In order to meet consumer expectations, the e-commerce sector is incurring higher  
5 costs and higher emissions, although only the former is transferred to users.

6 As future research, expanding the results of this study with regional and global supply networks is  
7 necessary. Maritime and air transport modes certainly have an impact on the level of emissions and  
8 could balance emissions between the line haul and the last mile. As already mentioned, sources of  
9 emissions other than transportation could be included in general calculations. The effects of  
10 electrification seen in this study as a sensitivity analysis could be confirmed with more in-depth case  
11 studies, and analyze specific electrification strategies in more detail.

## 12 **Acknowledgement**

13 This study was developed in the Department of Transport and Regional Economics of the University  
14 of Antwerp, with a team of researchers integrated by the authors and the special support of Mr. Tharun  
15 Vallabhaneni. Special acknowledge to BD Logistics for their financial support to this research.
