<b>Abstract:</b>	<p>According to Thompson's principle of similarity, the area of an object should be proportional to its length squared. However, leaf area-length data of some plants have been demonstrated not to follow the principle of similarity. We explore the reasons why the leaf area-length allometry deviates from the principle of similarity and also examine whether there is a general model describing the relationship among leaf area, width and length. More than 11,800 leaves from the six classes of woody and herbaceous plants were sampled to check the leaf area-length allometry. Six mathematical models were compared based on root-mean-square error as the measure of goodness-of-fit. The best supported model described a proportional relationship between leaf area and the product of leaf width and length (i.e., the Montgomery model). We found that the extent to which the leaf area-length allometry deviates from the principle of similarity depends upon the variation of the ratio of leaf width to length. Estimates of the parameter of the Montgomery model ranged between <math>1/2</math> and <math>\pi/4</math> for the six classes of plants. This is a narrower range than imposed by the limits <math>1/2</math> (for a triangular leaf with leaf length as its height and leaf width as its base) to <math>\pi/4</math> (for an elliptical leaf with leaf length as its major axis and leaf width as its minor axis). The narrow range in practice implies an evolutionary stability for the leaf area of large-leaved plants despite the fact that leaf shapes of these plants are rather different.</p>

19 **Abstract** According to Thompson's principle of similarity, the area of an object should be proportional to its  
20 length squared. However, leaf area-length data of some plants have been demonstrated not to follow the principle  
21 of similarity. We explore the reasons why the leaf area-length allometry deviates from the principle of similarity  
22 and also examine whether there is a general model describing the relationship among leaf area, width and length.  
23 More than 11,800 leaves from the six classes of woody and herbaceous plants were sampled to check the leaf area-  
24 length allometry. Six mathematical models were compared based on root-mean-square error as the measure of  
25 goodness-of-fit. The best supported model described a proportional relationship between leaf area and the product  
26 of leaf width and length (i.e., the Montgomery model). We found that the extent to which the leaf area-length  
27 allometry deviates from the principle of similarity depends upon the variation of the ratio of leaf width to length.  
28 Estimates of the parameter of the Montgomery model ranged between  $1/2$  and  $\pi/4$  for the six classes of plants.  
29 This is a narrower range than imposed by the limits  $1/2$  (for a triangular leaf with leaf length as its height and leaf  
30 width as its base) to  $\pi/4$  (for an elliptical leaf with leaf length as its major axis and leaf width as its minor axis).  
31 The narrow range in practice implies an evolutionary stability for the leaf area of large-leaved plants despite the  
32 fact that leaf shapes of these plants are rather different.

33

34 **Keywords** Allometry · Montgomery model · Leaf area · Leaf dimension · Thompson's principle of similarity

35

36 **Key message** Leaf area is proportional to the product of leaf length and width both for herbaceous and  
37 woody plants. The coefficient of proportionality ranges from  $1/2$  to  $\pi/4$  for investigated species.

38

## 39 **Introduction**

40 Thompson (1917) stated that the area of an object is proportional to the square of its length (the area-length  
41 allometry), and its weight is proportional to its area to the power  $3/2$  if the density of the object is regular (the  
42 weight-area allometry). These two proportionalities were referred to as the principle of similarity. Although the  
43 actual estimates for the power of the area-length allometry and that of the weight-area allometry in biology are not  
44 exactly equal to 2 and  $3/2$ , estimates from biological data often approximate those values. For instance, O'Shea  
45 et al. (2006) studied the allometric relationship between the surface and the length and that between the surface  
46 and the weight of six species of fish. The estimates of the exponent of the first allometry ranged from 1.88 to 2.22,  
47 and the estimates of the exponent of the second allometry ranged from 1.54 to 1.69.

48 These allometric relationships are also of special importance for leaves. Leaves, as important photosynthetic  
49 organs of plants, have been in the core of physiological and functional ecology and knowledge about the scaling  
50 of leaf dimension is important to understand ecosystem processes and plant life strategies (Westoby 1998; Wright  
51 et al. 2004). The leaf weight-area allometry has been reported for many leaves (Milla and Reich 2007; Li et al.  
52 2008; Sun et al. 2017; Lin et al. 2018). However, estimates of the exponent of the leaf weight-area allometry are  
53 usually lower than  $3/2$ . For instance, Milla and Reich (2007) explored the range of the estimates of the exponent  
54 of the leaf weight-area allometry using a large dataset of over 150 species. The mean estimated over all species  
55 they obtained was 1.10 with 95% confidence intervals ranging from 1.08 to 1.13 (the use of confidence intervals  
56 is of special importance in this regard, as they indicate the range of intraspecific variation of the exponent of the  
57 leaf weight allometry). Lin et al. (2018) studied the leaf weight-area allometry for bamboo species and found that  
58 the estimate of the exponent for the pooled data was 1.15 with a 95% confidence interval of 1.14 to 1.15. However,  
59 the exponent reported by both studies was far from the 1.5 calculated for the principle of similarity (Thompson  
60 1917). Lin et al. (2018) found that leaf weight was approximately proportional to leaf area to the power  $9/8$ . This  
61 indicates that leaf density decreases as leaf thickness increases. Other studies have verified that leaf thickness can  
62 affect the leaf weight-area allometry (Witkowski and Lamont 1991; Yano and Terashima 2004; Griffith et al. 2016).  
63 In comparison with leaf weight-area allometry, area-length allometry has been little studied, although there would  
64 be many advantages, such as an expression in dimensional terms of length and width of a leaf, which would be  
65 easy to measure in the field.

66 Many studies have provided parametric models to describe leaf shapes of some plants, especially for the  
67 plant family Poaceae. These models can be used to calculate leaf area. Dornbusch et al. (2011) proposed a general  
68 parameter model to depict the leaf shapes of wheat, barley and maize. Gielis (2003) proposed a superformula that

69 can be used to describe the shapes of many abiotic and biotic shapes, which has been simplified to fit to leaf  
70 dimensions. The simplified Gielis equation (SGE) has only two parameters of which one is related to leaf length,  
71 and another is related to the ratio of leaf width to length. Shi et al. (2015b) and Lin et al. (2016) used this simplified  
72 version to fit the leaf shapes of 46 bamboo species and found that the model generally performed well for the very  
73 similar leaf shapes of bamboos. Here, the corresponding estimates of the second parameter (related to the ratio of  
74 leaf width to length) only varied in a narrow range. Shi et al. (2018a) found that the simplified Gielis equation is  
75 also applicable to the leaves of other plants such as *Aucuba japonica* var. *variegata* Dombrain, *Chimonanthus*  
76 *praecox* (L.) Link, *Parrotia subaequalis* (H. T. Chang) R. M. Hao & H. T. Wei, *Phoebe sheareri* (Hemsl.) Gamble  
77 and *Pittosporum tobira* (Thunberg) W. T. Aiton. Leaf area for these species can be reliably estimated based on  
78 this simplified equation. However, these methods are only suitable for describing particular leaf shapes.  
79 Montgomery (1911) put forward a leaf-area formula for corn: leaf area ( $A$ ) =  $a_1 \times$  leaf length ( $L$ )  $\times$  leaf width ( $W$ ),  
80 where  $a_1$  is a constant to be fitted; leaf length is defined as the distance from leaf apex to leaf base; leaf width is  
81 defined as the maximum length of the segments perpendicular to the straight line passing through leaf apex and  
82 leaf base (Shi et al. 2018b). This model has been also demonstrated to be powerful in calculating leaf area for other  
83 plants such as castor, cotton, rice and sorghum (Jani and Misra 1966; Palaniswamy and Gomez 1974 and references  
84 therein). The Montgomery model has been widely applied to calculate the area of herbaceous plants, especially  
85 for crops. However, there are only a few studies that have reported its validity for calculating the leaf area of  
86 woody plants. For instance, Verwijst and Wen (1996) used the Montgomery model to fit data on leaf area, length  
87 and width of basket willow (*Salix viminalis* L.). In addition, they also compared this model with other models  
88 using leaf area as the response variable with leaf length (or leaf width) as the explanatory variable. They found  
89 that the Montgomery model was the best among these models. Since then no further studies have focused on the  
90 leaves of woody plants. In addition, the previous studies all used a single species without using extra species to  
91 test the model's validity. If the Montgomery model holds for most broad-leaved plants, then whether or not  
92 Thompson's principle of similarity holds in these plants depends upon the relationship between leaf width and  
93 length. The principle of similarity will hold if there is a proportional relationship between leaf width and length;  
94 if so, the estimate of the exponent for the leaf area-length allometry will equal 2. Otherwise the exponent will  
95 deviate from 2. Furthermore, the leaf weight-area allometry is affected in a similar way.

96 In this contribution, we used six plant morphological groups to test the validity of the Montgomery model:  
97 10 populations of *Parrotia subaequalis* (H. T. Chang) R. M. Hao & H. T. Wei, 5 species of Lauraceae, 2 species  
98 of tulip trees with their hybrid, 5 species of Oleaceae, 12 species of Bambusoideae, and 12 species of Rosaceae.

99 In addition, we also examined a set of other leaf-area allometric models to test whether the Montgomery model  
100 was the best-performing for fitting the observed data.

101

## 102 **Materials and methods**

### 103 **Collection information**

104 The leaves of 10 populations of *P. subaequalis* (with 150 leaves or so for each population) were collected in Eastern  
105 China from July to September, 2016 (see Table S1 in Electronic Supplementary Material); the leaves of 5 species  
106 of Lauraceae (each species  $\geq 300$  leaves) were collected in the Nanjing Forestry University campus, China from  
107 late August to early October, 2018 (see Table S2 in Electronic Supplementary Material); the leaves of American  
108 tulip trees (*Liriodendron chinense* (Hemsl.) Sarg.) and Chinese tulip trees (*Liriodendron tulipifera* Linn.) with  
109 their hybrid (*Liriodendron chinense*  $\times$  *tulipifera* P. Z. Ye) (each species  $\geq 170$  leaves) were collected in Nanjing,  
110 China on 11 October, 2017 (see Table S3 in Electronic Supplementary Material); the leaves of 5 species of  
111 Oleaceae (each species  $\geq 300$  leaves) were collected in the Nanjing Forestry University campus, China from late  
112 August to early October, 2018 (see Table S4 in Electronic Supplementary Material); the leaves of 12 bamboo  
113 species (with 100–500 leaves for each species) were collected in the Nanjing Forestry University campus, China  
114 from early July of 2014 to early July of 2018 (see Table S5 in Electronic Supplementary Material); and the leaves  
115 of 12 species of Rosaceae (each species  $\geq 300$  leaves) were collected in the Nanjing Forestry University campus,  
116 China from late April to early May, 2018 ( see Table S6 in Electronic Supplementary Material).

117

### 118 **Data acquisition**

119 Leaves were scanned to bitmap format (used scanner: Aficio MP 7502; Rocoh, Japan). The image resolution was  
120 400 dpi. Then, we used Matlab (version  $\geq 2009a$ ) procedures proposed by Shi et al. (2015a, 2018a) to extract the  
121 leaf profile data. The R procedures proposed by Shi et al. (2018a) were then used to adjust the leaf profile data and  
122 calculate leaf area, length and width.

123

### 124 **Statistical analysis**

125 We used six models to fit leaf area data (Table 1). For simplification, we will refer to the parameter of model 1 as  
126 the Montgomery parameter below. We used the log-log method to stabilize the variance of the observations of leaf  
127 area in data fitting (Table 1) because many biological measures exhibited a power-function relationship between  
128 the variance and mean that implies heteroscedasticity (Shi et al. 2017). Model fitting was carried out using least-

129 squares linear regression to estimate the parameters. For models 2–4, we calculated the 95% and 99.7% confidence  
130 intervals of the slope (which correspond to the estimate of the slope  $\pm 1.96$  times its standard deviation and to the  
131 estimate of the slope  $\pm 3$  times its standard deviation, respectively). By this means, we tested whether model 2  
132 could be simplified to model 1. Our criterion was that if the 99.7% confidence intervals of the slope of model 2  
133 for most data sets included 1, then that indicated that model 2 could be replaced by model 1. Here, 95% confidence  
134 intervals also served as a reference.

135 To measure the goodness of fit of the linear regression, we took the root-mean-square error (RMSE):

$$136 \quad \text{RMSE} = \sqrt{\frac{\sum_{i=1}^n (y_i - \hat{y}_i)^2}{n}} \quad (1)$$

137 Here,  $y$  represents the natural logarithm of leaf area; the subscript  $i$  represents the  $i$ -th leaf; and the circumflex on  
138 the  $y$  represents the predicted value using a model.

139 After finding the best model, we used the pooled data for every class of plants to test whether there were  
140 significant differences in the estimates of a particular parameter of interest among the six classes. For this purpose,  
141 we used the bootstrap percentile method (Efron and Tibshirani 1993; Sandhu et al. 2011) to test the significance  
142 of the differences among the parameter estimates. For example, if model 1 was the best, we were concerned with  
143 whether the estimates of the constant  $a_1$  (Table 1) for six classes of plants were significantly different.

144

#### 145 **Statistical software**

146 Matlab (version R2009a) was used to extract leaf profile data from the scanned bitmap image (Shi et al., 2015a,  
147 2018a). R (version 3.2.2; R Core Team 2015) was used to carry out the statistical calculations. Packages ‘spatstat’  
148 (version 1.43-0.025) and ‘splancs’ (version 0.4-19) were used to adjust leaf profile data and to calculate leaf area.

149

#### 150 **Results**

151 Model 2 consistently has the lowest RMSE, with the RMSE of model 1 (namely the Montgomery model) being  
152 slightly higher than that of model 2 (Table S7 in Electronic Supplementary Material shows the RMSEs of the 37  
153 data sets). Models 3–6 always have a worse goodness of fit than models 1–2. Figs. 1–6 exhibit the fitted results  
154 using model 1. The estimates of the parameters of models 1–6 are listed in Table S8 in Electronic Supplementary  
155 Material. The estimates of the parameter of model 1 among 47 data sets ranged from  $-0.56$  to  $-0.30$ , and the  
156 corresponding values of the antilogarithm (namely the Montgomery parameter) varied in a small range from 0.57  
157 to 0.74. The 95% confidence intervals of these estimates all fall into the range  $(0.5, \pi/4)$  (Figs. 1–4). Although

158 model 2 had a slightly better goodness of fit than model 1, the estimates of the slope of model 2 did not substantially  
159 deviate from unity. There were 21 among 47 data sets whose 99.7% confidence intervals (i.e., the estimate  $\pm 3$   
160 standard deviations) included 1. In the remaining 26 data sets, the lower bounds (or upper bounds) of the 99.7%  
161 confidence intervals differed from unity by less than 0.05 except for data sets 30 (*Indosasa sinica* C. D. Chu et C.  
162 S. Chao) and 41 (*Kerria japonica* (L.) DC.). It is worth pointing out that the leaves of *K. japonica* are more  
163 bilaterally asymmetric than those of the other species of Rosaceae investigated. That means that the scanned leaf  
164 length, defined as the distance in a straight line from leaf apex to leaf base, will not closely correspond to the  
165 position of the leaf's main vein.

166 Fig. 7 shows the fitted results for the pooled leaf-area data for each of the six classes of plant. The goodness  
167 of fit is high, with the correlation coefficient exceeding 0.98 for each of the six classes. There were significant  
168 differences in the estimates of the Montgomery parameter among the six classes. The estimates of the Montgomery  
169 parameter for the pooled data of *Liriodendron* and Bambusoideae were significantly higher than those of other  
170 classes (Fig. 8). Overall, there was a significant difference in the estimate of the Montgomery parameter between  
171 any two classes of plants.

172

## 173 **Discussion**

### 174 **Influence of the relationship between leaf length and width on the principle of similarity**

175 The Montgomery model has been confirmed to be valid in predicting the leaf areas of many crops (Jani and Misra  
176 1966; Palaniswamy and Gomez 1974 and references therein), but it has not been used to analyze leaf area-length  
177 allometry. If leaf area is proportional to the product of leaf length and width, then it follows that the relationship  
178 between leaf length and width will affect the leaf area-length allometry. If leaf length is proportional to leaf width,  
179 leaf area will be proportional to leaf length squared (or leaf width squared). This will be in line with the principle  
180 of similarity. To test this hypothesis, we calculated the coefficients of variation (CVs) in the ratio of leaf width to  
181 length for each species (Fig. 9a) and checked whether the CVs were related to the RMSE values of model 5. Indeed,  
182 the correlation coefficient of model 5 reached 0.85 ( $P < 0.01$ ), thereby supporting the principle of similarity (Fig.  
183 9b). This means that the scaling stability of leaf shape, which denotes that the ratio of leaf width to length for  
184 leaves of different sizes is approximately constant, will determine whether there is a good proportional relationship  
185 between leaf area and leaf length squared. The simplified Gielis equation (SGE) has been demonstrated to be a  
186 good approach to describe the leaf shapes of bamboos (Gielis 2003; Shi et al. 2015b; Lin et al. 2016, 2018). Lin et  
187 al. (2018) demonstrated mathematically that leaf area is proportional to leaf length squared on the condition that

188 the leaf-shape parameters for leaves have a small variation. The leaf shapes of bamboos were very similar to each  
189 other, so that model 5 fits their data well. However, although the ratios of leaf width to length of bamboos are  
190 significantly lower than those of the other five groups of plants (Fig. 7A), the CVs of the ratios of leaf width to  
191 length were not significantly lower than those of the others. Surprisingly, despite the complex leaf shapes of tulip  
192 trees, their CV of the ratios of leaf width to length were very low, lower than for the other plants investigated.  
193 American and Chinese tulip trees exhibit a certain difference in leaf shape, even though both species are closely  
194 related (Fang, 1994). For example, the angle formed by two lobes on the leaf top of American tulip trees is usually  
195 smaller than that of leaves of Chinese tulip trees. However, Shi and Liu (2018) reported that there was no  
196 significant difference in leaf bilateral symmetry measures among the two species and their hybrid. Thus, we had  
197 grounds for believing that the leaves of tulip trees might exhibit a type of uniform isotropic growth in different  
198 directions from the leaf margin (Coen et al. 2004). This should be a major cause of the small variation in the ratios  
199 of leaf width to length. Verwijst and Wen (1996) studied the leaf allometry of basket willow (*S. viminalis*) and  
200 found that the ratio of leaf width to length decreased with increasing leaf length. We calculated the correlation  
201 coefficients of leaf length and the *W/L* ratio for 47 data sets and found that most data sets exhibited a negative  
202 correlation. Additionally, we calculated the estimate of the slope of the linear equation between the *W/L* ratio and  
203 leaf length for each data set, and the slopes associated with the significant correlations were larger than  $-1$ . This  
204 indicated that the significance of the correlation did not result from the negative relationship between  $1/L$  and  $L$   
205 itself (see Table S9 in Electronic Supplementary Material). The correlations of 32 of the 47 data sets were  
206 significant, indicating that the *W/L* ratio decreased with increasing leaf size. However, the correlations for the  
207 remaining 15 data sets were insignificant as all have lower CV values. This meant that the *W/L* ratios representing  
208 leaf shapes for these plants remained stable among different individual leaves.

209

### 210 **About two kinds of special leaf shapes**

211 All estimates for the Montgomery parameter range from 0.5 to  $\pi/4$  (Figs. 1–6). That is in line with previous  
212 findings on the Montgomery parameter of other species (Jani and Misra 1966; Palaniswamy and Gomez 1974;  
213 Verwijst and Wen 1996; de Swart et al. 2004). However, challenges remain how to discern the factors that most  
214 strongly influence the estimate of the Montgomery parameter. That could, however, be solved by the comparison  
215 of two major leaf shape functions, the SGE (Shi et al. 2015b) and the area formula of a triangle (i.e., area =  
216  $1/2 \times \text{base} \times \text{height}$ ). The SGE performed well in fitting the leaf shapes of some plants. It is usually given in the polar  
217 coordinate form:

218 
$$r = \frac{l}{\left(\cos \frac{\varphi}{4} + \sin \frac{\varphi}{4}\right)^{1/n}} \quad (2)$$

219 where  $r$  and  $\varphi$  are the polar coordinates and  $n$  and  $l$  are parameters to be fitted.  $\varphi$  ranges from 0 to  $2\pi$ . Shi et al.  
 220 (2018a) demonstrated that these two parameters could be mathematically expressed by leaf width and length. The  
 221 area of the SGE was then equal to:

222 
$$A = \frac{1}{2} \int_0^{2\pi} r^2 d\varphi \quad (3)$$

223 When  $n$  is a constant for different individual leaves, the following will be true:  $A \propto L^2$  (Lin et al. 2018). In other  
 224 words, the ratio of leaf width to length is a constant. However, despite the fact that the leaves were from the same  
 225 species, there was a certain degree of intraspecific variation in the ratio of leaf width to length (Fig. 9a). Apparently,  
 226 a larger variation of the ratio of leaf width to length will result in a lower goodness of fit. Thus, Eq. (3) with a  
 227 constant  $n$  can be regarded as a special case of the Montgomery model where leaf width is proportional to leaf  
 228 length (namely a constant ratio of leaf width to length). The smaller  $n$  is, the smaller the estimate of the  
 229 Montgomery parameter is; and vice versa. When  $n$  goes to infinity,  $r$  will be a constant ( $= L/2$ ) based on Equation  
 230 2. As a result, Eq. (3) is actually the area of a circle. This means that the Montgomery parameter equals  $\pi/4$ .  
 231 Triangular leaves could be considered to be another extreme form of leaf shape in plants. For truly triangular leaves,  
 232 the Montgomery parameter would be 0.5. For *Polygonum perfoliatum* L., whose leaf shape is similar to that of an  
 233 equilateral triangle (Kumar and DiTommaso 2005), our estimate of the Montgomery parameter was 0.55 (Fig.  
 234 10a). In fact, the shape of the leaves of *P. perfoliatum* is better described as hastate, which describes the shape of  
 235 an arrow with a pair of outward-pointed lobes at its base. This may explain why the observed Montgomery  
 236 parameter exceeds 0.5. Interestingly, the estimate of the exponent of leaf area-length allometry of this plant  
 237 approaches 2 (Fig. 10b).

238 Leaf shape is essentially determined by genes (Sicard et al. 2014), and the leaf shape diversity of the  
 239 Brassicaceae family for instance is related to regulatory evolution coupled with gene duplication and loss by  
 240 modifying local growth pattern during organogenesis (Vlad et al. 2014). However, the veins also play a significant  
 241 role on blade growth directions (Runions et al. 2017). A hub-and-spoke vein pattern usually leads to a circular leaf  
 242 shape, e.g. the common pennywort (*Hydrocotyle vulgaris* L.), so that the distance from any point on the leaf edge  
 243 to its center approaches a constant to keep a high transformation efficiency of water, inorganic salts and nutrients.  
 244 Most leaf shapes, such as deltoid, lobed, ovate, obovate, palmate and truncate, are related to the dendritic vein  
 245 pattern. The areas of these leaves are obviously smaller than that of an ellipse whose major axis is defined as leaf

246 length and minor axis is defined as leaf width. Although there are some leaves whose shapes approach an ellipse,  
247 the part at the base or at the tip is usually narrower than that at the converse position (at tip or at base), which  
248 results in an asymmetrical ‘elliptical’ shape. Thus, we believe that the estimates of the Montgomery parameter for  
249 different broad-leaved plants should be in the range of  $(1/2, \pi/4)$ .

250

## 251 **Conclusion**

252 We showed that the Montgomery model is well suited to calculate the area of a leaf by using its length and width.  
253 Different leaf shapes did not affect the model accuracy, which further provided important insight to uncover the  
254 secret of the leaf-area allometry. However, additional species with extreme leaf shapes should be included in future  
255 studies to test if the Montgomery model qualifies as the most robust model for all leaf shapes. Our findings also  
256 further advance our knowledge about leaf morphologies and correlation between leaf dimensions. The  
257 Montgomery model was the most parsimonious of all our models tested and thus allows for easy application for  
258 leaf area calculations. That makes the Montgomery model particularly useful for application in field studies as it  
259 provides highly accurate estimates of leaf area based on its length and width. Leaf area is one of the most important  
260 plant traits, but *in situ* measurements and measurements under remote field conditions still impose major  
261 challenges. Knowledge about robust models predicting leaf area from easily measured leaf dimensions, as width  
262 and length, could solve those problems.

263

264 **Author contribution statement** ML, JS, XY, PW, LZ and ZL collected the leaves and carried out the work of  
265 image processing; the manuscript were written by PS, DAR, JG and JS; PS and JS designed the experiments; PS  
266 and DAR analyzed the data. All authors read and commented on this manuscript.

267

268 **Acknowledgments** We thank Liang Cheng, Yanming Fang, Shuyan Lin and Xiao Zheng for their help during the  
269 leaf collection. This work was nominally financially supported the Priority Academic Program Development of  
270 Jiangsu Higher Education Institutions.

363 **Fig. 1** Comparison of the leaf-area observed and predicted values of the 10 geographical populations of *P.*  
364 *subaequalis*. *A* represents leaf area; *L* represents leaf length; *W* represents leaf width; RMSE represents the root-  
365 mean-square error; *r* represents the correlation coefficient of the observed and predicted values of leaf area; *n*  
366 represents the sample size of leaves;  $\exp(\hat{a}_1)$  represents the estimate of the Montgomery parameter; 95% CI  
367 represents the 95% confidence interval of the Montgomery parameter. Population ‘XX’ represents the population  
368 code (see Table S1 in Electronic Supplementary Material for details).

369 **Fig. 2** Comparison of the leaf-area observed and predicted values of the 5 species of Lauraceae. *A* represents leaf  
370 area; *L* represents leaf length; *W* represents leaf width; RMSE represents the root-mean-square error; *r* represents  
371 the correlation coefficient of the observed and predicted values of leaf area; *n* represents the sample size of leaves;  
372  $\exp(\hat{a}_1)$  represents the estimate of the Montgomery parameter; 95% CI represents the 95% confidence interval of  
373 the Montgomery parameter (see Table S2 in Electronic Supplementary Material for details).

374 **Fig. 3** Comparison of the leaf-area observed and predicted values of American and Chinese tulip trees and their  
375 hybrid. *A* represents leaf area; *L* represents leaf length; *W* represents leaf width; RMSE represents the root-mean-  
376 square error; *r* represents the correlation coefficient of the observed and predicted values of leaf area; *n* represents  
377 the sample size of leaves;  $\exp(\hat{a}_1)$  represents the estimate of the Montgomery parameter; 95% CI represents the  
378 95% confidence interval of the Montgomery parameter (see Table S3 in Electronic Supplementary Material for  
379 details).

380 **Fig. 4** Comparison of the leaf-area observed and predicted values of the 5 species of Oleaceae. *A* represents leaf  
381 area; *L* represents leaf length; *W* represents leaf width; RMSE represents the root-mean-square error; *r* represents  
382 the correlation coefficient of the observed and predicted values of leaf area; *n* represents the sample size of leaves;  
383  $\exp(\hat{a}_1)$  represents the estimate of the Montgomery parameter; 95% CI represents the 95% confidence interval of  
384 the Montgomery parameter (see Table S4 in Electronic Supplementary Material for details).

385 **Fig. 5** Comparison of the leaf-area observed and predicted values of the 12 bamboo species. *A* represents leaf  
386 area; *L* represents leaf length; *W* represents leaf width; RMSE represents the root-mean-square error; *r* represents  
387 the correlation coefficient of the observed and predicted values of leaf area; *n* represents the sample size of leaves;  
388  $\exp(\hat{a}_1)$  represents the estimate of the Montgomery parameter; 95% CI represents the 95% confidence interval of  
389 the Montgomery parameter (see Table S5 in Electronic Supplementary Material for details).

390 **Fig. 6** Comparison of the leaf-area observed and predicted values of the 12 species of Rosaceae. *A* represents  
391 leaf area; *L* represents leaf length; *W* represents leaf width; RMSE represents the root-mean-square error; *r*

392 represents the correlation coefficient of the observed and predicted values of leaf area;  $n$  represents the sample size  
393 of leaves;  $\exp(\hat{\alpha}_1)$  represents the estimate of the Montgomery parameter; 95% CI represents the 95% confidence  
394 interval of the Montgomery parameter (see Table S6 in Electronic Supplementary Material for details).

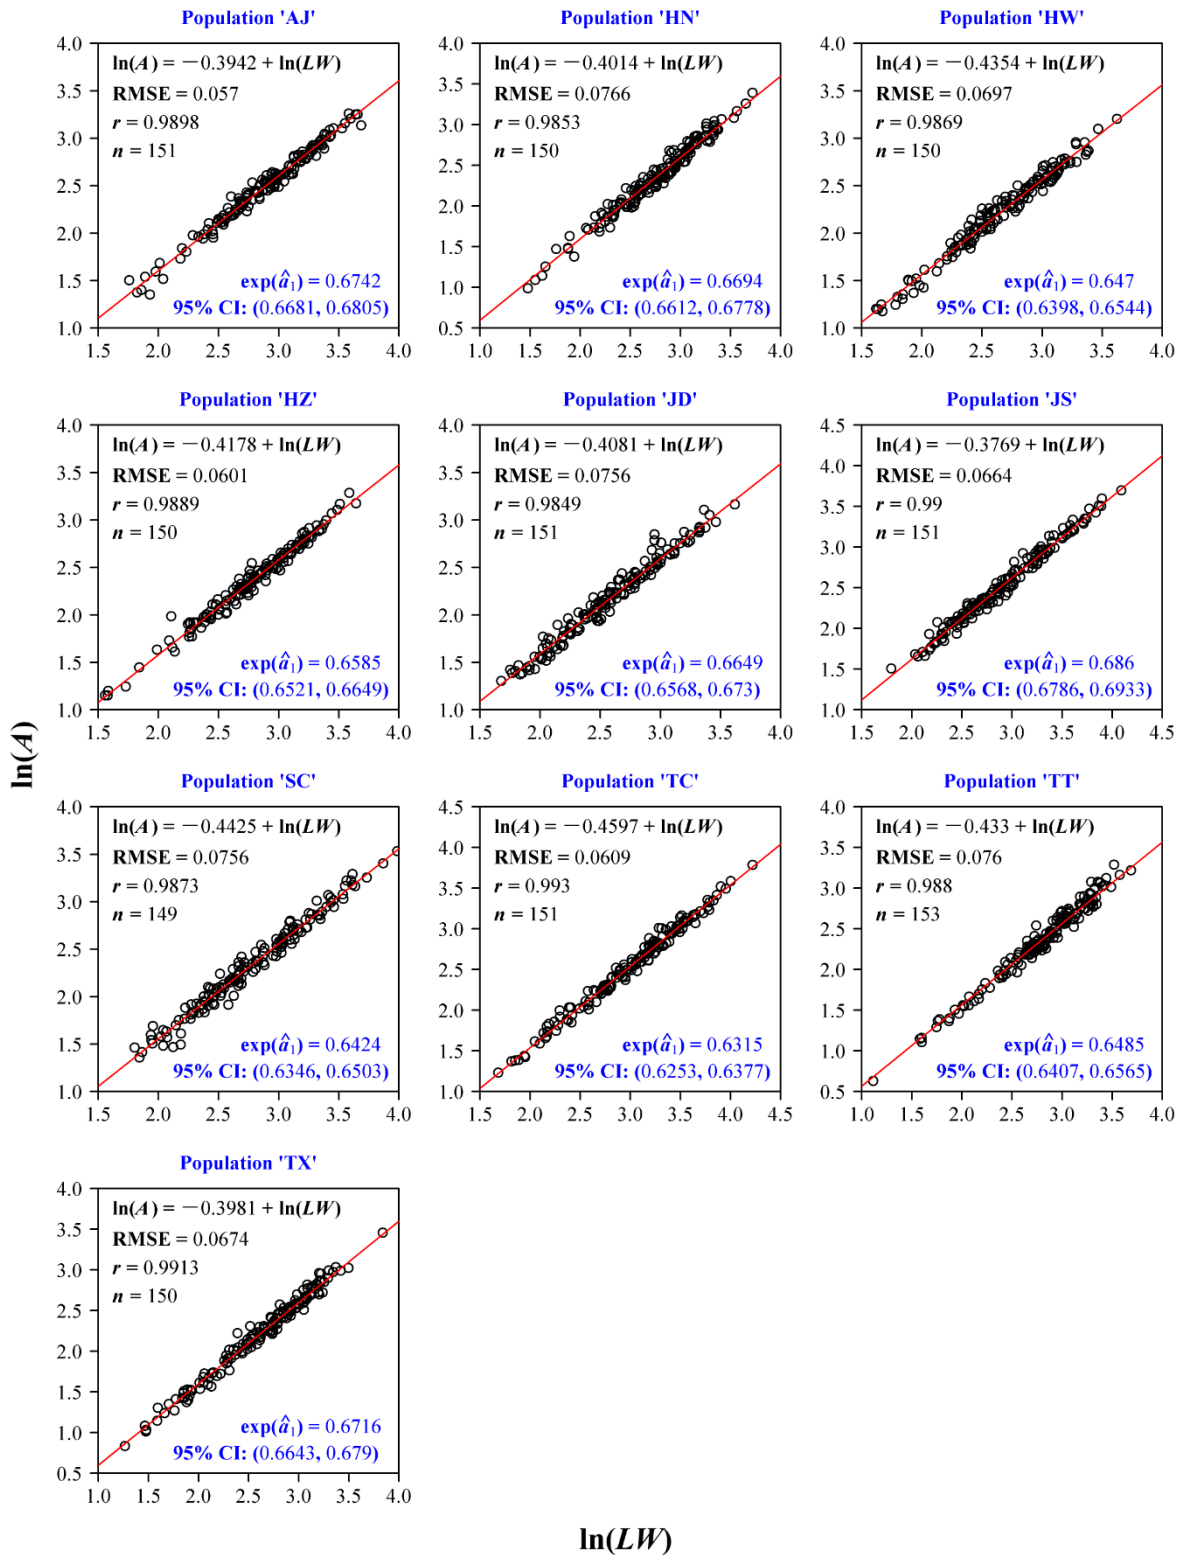

395 **Fig. 7** Comparison of the leaf-area observed and predicted values of the six classes of plants. The open circles  
396 in every panel represent the pooled data of each class of plants; different colors represent different species (or  
397 different geographical populations of the same species for the first panel) in every panel.

398 **Fig. 8** Comparison of the estimates of the Montgomery parameter among the six classes of plants. The letters A,  
399 B, C, D, E and F on the top of each box exhibit the significance of difference.  $A > B > C > D > E > F$ .

400 **Fig. 9** Boxplot of the ratios of leaf width to length among 47 data sets from six classes of plants and the  
401 relationship between the coefficient of variation in the  $W/L$  ratios and root-mean-square error. The numbers on or  
402 below the boxplot in panel **a** represent the coefficients of variation in the ratio of leaf width to length; the numbers  
403 around the regression straight line in panel **b** represent RMSE values corresponding to different CV values for 47  
404 data sets.

405 **Fig. 10** Comparison of the predicted results using the actual leaf data of *P. perfoliatum* and simulated leaf data.  
406 Panel **a** exhibits the 95% confidence interval (CI) of the estimate of the Montgomery parameter (namely the  
407 intercept), and panel **b** exhibits the 95% confidence interval (CI) of the estimate of the slope.

438

440 **Table 1** Six leaf-area allometric models used in this study.

Model no.	Model	Log-transformed model
Model 1	$A = c_1 (LW)$	$\ln(A) = a_1 + \ln(LW)$
Model 2	$A = c_2 (LW)^{b_2}$	$\ln(A) = a_2 + b_2 \ln(LW)$
Model 3	$A = c_3 L^{b_3}$	$\ln(A) = a_3 + b_3 \ln(L)$
Model 4	$A = c_4 W^{b_4}$	$\ln(A) = a_4 + b_4 \ln(W)$
Model 5	$A = c_5 L^2$	$\ln(A) = a_5 + 2\ln(L)$
Model 6	$A = c_6 W^2$	$\ln(A) = a_6 + 2\ln(W)$

441 Here, for the first model,  $c_1 = \exp(a_1)$ , and there are the similar relationships between the pre-exponential  
442 constants and the intercepts for the other models.  $A$  represents leaf area;  $L$  represents leaf length;  $W$  represents leaf  
443 width; the other letters represents constants to be fitted.
