We report on a search for the standard-model Higgs boson in  $p\bar{p}$  collisions at  $\sqrt{s} = 1.96$  TeV using an integrated luminosity of  $2.0 \text{ fb}^{-1}$ . We look for production of the Higgs boson decaying to a pair of bottom quarks in association with a vector boson  $V$  ( $W$  or  $Z$ ) decaying to quarks, resulting in a four-jet final state. Two of the jets are required to have secondary vertices consistent with  $B$ -hadron decays. We set the first 95% confidence level upper limit on the  $VH$  production cross section with  $V(\rightarrow q\bar{q}/qq')H(\rightarrow b\bar{b})$  decay for Higgs boson masses of 100–150 GeV/ $c^2$  using data from run II at the Fermilab Tevatron. For  $m_H = 120 \text{ GeV}/c^2$ , we exclude cross sections larger than 38 times the standard-model prediction.

The standard model (SM) of elementary particle physics includes a scalar Higgs ( $H$ ) boson to explain the origins of electroweak-symmetry breaking [1,2]. Direct searches for the Higgs scalar boson at the LEP collider [3] have constrained the Higgs boson mass ( $m_H$ ) to be greater than  $114.4 \text{ GeV}/c^2$  at 95% confidence level (C.L.). For Higgs boson masses above this limit, the CDF and D0 experiments at the Tevatron collider are currently performing the most sensitive searches [4], and have excluded Higgs boson masses between 160 and 170  $\text{GeV}/c^2$  [5]. Global fits to electroweak data [6] indicate a light SM Higgs boson, excluding  $m_H > 163 \text{ GeV}/c^2$  at 95% C.L. Searches for a low-mass Higgs boson are thus particularly relevant. For  $m_H < 135 \text{ GeV}/c^2$ , the dominant decay mode is  $H \rightarrow b\bar{b}$  [7]. While the dominant production modes are direct  $gg \rightarrow H$  and  $q\bar{q} \rightarrow H$ , the  $b\bar{b}$  signature in this channel is overwhelmed by background from  $b\bar{b}$  production. Searches for events where the Higgs boson is produced in association with a vector boson ( $V = W$  or  $Z$ ) are more promising. The  $VH$  associated production cross section is smaller by an order of magnitude than for direct production, but identification of the accompanying vector boson reduces the multijet background, making searches for  $VH$  the most sensitive ones at low Higgs boson mass.

So far, Tevatron run II searches [8,9] have used signatures where the  $V$  decays to leptons. In this Letter we report on an analysis of the channel in which the  $V$  decays to a  $q\bar{q}$  pair resulting in two jets. Using data from  $2.0 \text{ fb}^{-1}$  of integrated luminosity collected by the CDF experiment, we search for four-jet events compatible with the  $VH$  decay. While this channel has a large multijet background, it benefits from the combined cross sections of  $ZH$  and  $WH$  production as well as the large  $V \rightarrow q\bar{q}/q'q'$  branching ratio of about 70% [10]. An analysis of this channel in run I of the Tevatron [11] suggests strong potential. This Letter presents the first analysis of this channel using data from run II of the Tevatron; we find that uncertainties on the dominant background are larger than had been anticipated [12].

The CDF II detector [13,14] consists of a cylindrical magnetic spectrometer surrounded by sampling calorimeters used to measure the energies of the jets. Charged particle tracking is performed with silicon microstrip detectors surrounded by a cylindrical multilayer drift chamber, immersed in a solenoidal magnetic field. Planar drift chambers surround the calorimeters to detect muons.

The data were collected using a multijet on-line event selection (trigger) [15], originally designed for hadronic top decays. To trigger a jet, in the first stage (level 1) a single calorimeter tower was required with a transverse energy ( $E_T$ ) [16] of at least 10 (20) GeV for the data from the first (second)  $\text{fb}^{-1}$  of integrated luminosity. At level 2, clusters of contiguous calorimeter towers were identified

and a fast on-line cluster energy measurement was performed. Four clusters with  $E_T > 15 \text{ GeV}$  were required. Additionally, the total transverse energy,  $\sum E_T$ , was required to exceed 125 (175) GeV for the first 0.4 (last 1.6)  $\text{fb}^{-1}$  to reduce backgrounds from soft jets. The thresholds were increased in the later periods to maintain an acceptable trigger rate as the instantaneous luminosity increased over time.

The trigger efficiency for the  $VH$  signal is estimated using PYTHIA [17] simulated events, corrected to describe the observed trigger performance in the data. Interaction of the final-state particles with the CDF II detector is described by a GEANT-based detector simulation [18]. The data used to measure the efficiency corrections were collected by triggers which required a single jet with  $E_T$  greater than 20 or 50 GeV. Corrections to the simulated  $VH$  trigger efficiency were derived by comparing these data to multijet simulations with the corresponding thresholds. The corrections account for differences in the energy scale at the trigger level between data and simulation and for imperfect simulation of soft hadrons and jet finding in the trigger algorithm. These corrections result in a relative reduction of the estimated efficiency for the  $VH$  signal by  $\sim 20\%$ . A systematic uncertainty of 7% (relative) on the trigger efficiency is derived by comparing the corrections found in data with different single-jet energy thresholds, and in different data periods. The overall trigger efficiency for the  $VH$  signal (with  $m_H = 120 \text{ GeV}/c^2$ ) is  $33 \pm 2\%$  ( $17 \pm 1\%$ ) for the  $\sum E_T$  threshold of 125(175) GeV.

In the final off-line selection, jets are identified in the calorimeters by the JETCLU [19] algorithm with a clustering radius of 0.4 in azimuth-pseudorapidity space. The reconstructed jet energies are corrected for effects of calorimeter response, multiple  $p\bar{p}$  interactions, the underlying event, and energy deposited outside the clustered jet [20]. Jets originating from  $b$  quarks are identified, or “ $b$ -tagged,” by the SECVTX [21] algorithm, which searches for a secondary vertex that results from the displaced decay of a  $B$  hadron.

Events compatible with the  $VH \rightarrow qqbb$  signature are selected by requiring at least four jets with  $|\eta| < 2.4$  and  $E_T > 15 \text{ GeV}$  in which exactly two of the jets are  $b$ -tagged. The invariant mass of the  $b$ -tagged jets,  $m_{bb}$ , is required to exceed  $75 \text{ GeV}/c^2$ . The invariant mass of the remaining leading two  $q$  jets,  $m_{qq}$ , is required to be compatible with the  $W$  or  $Z$  mass:  $35 < m_{qq} < 120 \text{ GeV}/c^2$ . The di-jet mass resolution in the relevant invariant mass range is of the order of  $15 \text{ GeV}/c^2$  [22], so the  $WH$  and  $ZH$  channels cannot be distinguished. We refer to this as the *signal* region; see Fig. 1. Events in other regions of the  $(m_{bb}, m_{qq})$  plane and events with at least one  $b$ -tag are used to model the multijet background to the  $VH \rightarrow qqbb$  signature. Events with identified isolated leptons are removed from the sample. The combined trigger and selec-

FIG. 1. Regions in the plane of  $m_{bb}$ , invariant mass of the two  $b$ -jets, and  $m_{qq}$ , invariant mass of the two other jets. The *tag* and *tune* regions are used to define and tune the tag rate function used to predict the background contribution from  $b\bar{b}$  production in the *signal* region. The *control* region is used to estimate a systematic uncertainty on the interpolation of the tag rate function into the *signal* region.

tion efficiency for  $VH \rightarrow qqbb$  events for the entire data-taking period varies from  $\sim 1\%$  to  $\sim 4\%$  for Higgs boson masses between 100 and 150  $\text{GeV}/c^2$ .

The dominant background to the  $qqbb$  final state is multijet production. In order to distinguish between signal and background events, we use the log-likelihood ratio  $Q(\mathbf{x}) = \log[(P(\mathbf{x})_{WH} + P(\mathbf{x})_{ZH})/P(\mathbf{x})_{QCD}]$  where  $\mathbf{x}$  is the vector of measured jet momenta of the four highest  $E_T$  jets, and  $P(\mathbf{x})_{WH}$ ,  $P(\mathbf{x})_{ZH}$ , and  $P(\mathbf{x})_{QCD}$  are the likelihoods of observing the event  $\mathbf{x}$  for the  $WH$ ,  $ZH$ , and  $QCD$  processes, respectively. The likelihoods are calculated by convoluting the differential cross section as a function of the incoming and outgoing quark momenta for the processes with parametrized detector resolution functions, and numerically integrating over the magnitudes of the quark momenta [23].  $P(\mathbf{x})_Y$  is defined as

$$P(\mathbf{x})_Y = \int d\Phi |\mathcal{M}_Y|^2 P_{\text{tot}} \prod_{j=1\dots 4} T(E_{\text{jet}}^j | E_{\text{quark}}^j) f_p f_{\bar{p}},$$

where  $d\Phi$  is the phase space of the incoming and outgoing quark momenta,  $\mathcal{M}$  is the matrix element,  $P_{\text{tot}}$  is the probability density of the transverse momentum of the process described by the matrix element,  $T(E_{\text{jet}} | E_{\text{quark}})$  is a transfer function which parametrizes the probability to measure a quark of energy  $E_{\text{quark}}$  as a jet with energy  $E_{\text{jet}}$ , and  $f_p$  and  $f_{\bar{p}}$  are the parton distribution functions [24] for the proton and antiproton.

The matrix elements for  $WH$  and  $ZH$  are numerically calculated by the ALPGEN [25] simulation. The matrix element  $\mathcal{M}_{gg \rightarrow ggbb}$  is used to describe the dominant background process and is calculated by the MADGRAPH [26] simulation. However, these matrix elements do not describe initial state radiation, which could result in nonzero

total transverse momentum of the  $VH$  system. The probability density of the transverse momentum,  $P_{\text{tot}}$ , is extracted from simulated PYTHIA events that include radiation.

Models of the  $Q$  likelihood ratio distribution are constructed for both signal and background events. Backgrounds from  $t\bar{t}$ , single top, and diboson production are modeled by PYTHIA, but normalized to next-to-leading order calculations. ALPGEN is used to simulate the leading-order multiparton final state for the  $W$  with heavy-flavor jets background, while the hadronization and parton showering are modeled by PYTHIA. Systematic uncertainties in the signal acceptance, which includes trigger and selection efficiency, and the shape of the signal in  $Q$ , come from rates of initial- and final-state radiation, the jet energy scale, the parton distribution functions, the trigger acceptance, and the  $b$ -tagging efficiency. Uncertainties in the cross sections of the background processes contribute to the systematic uncertainty in the background model.

A model for the primary background is constructed from the data using the background-dominated sample with at least one  $b$ -tagged jet. Each of the additional jets, called a *probe* jet, is weighted by the probability for it to receive a  $b$ -tag, called the tag rate function (TRF). For an event to contribute to the background model in the signal region, the invariant mass of the tagged jet and the probe jet must exceed 75  $\text{GeV}/c^2$  and the mass of the other two leading jets,  $m_{qq}$ , in the event must be between 35 and 120  $\text{GeV}/c^2$ . Combinations outside this window represent an orthogonal set of probe jets, which was used to measure the TRF. In particular, the TRF is measured on combina-

FIG. 2 (color online). Systematic uncertainties on the number of events expected for the multijet background model as a function of the discriminant  $Q$ , from three sources described in the text. Relative uncertainties are shown in the lower pane.

FIG. 3 (color online). Predicted and observed distribution of the  $Q$  discriminant in the signal region (see Fig. 1) in  $2.0 \text{ fb}^{-1}$  of integrated luminosity. Lower pane shows data with the dominant QCD contribution subtracted.

tions where the mass of the other two jets is incompatible with the vector boson masses,  $m_{qq} < 25 \text{ GeV}/c^2$  or  $m_{qq} > 130 \text{ GeV}/c^2$  (the region labeled *tag* in Fig. 1).

The tag rate is a function of four variables: the  $p_T$  of the probe jet, the number of tracks in the probe jet that traverse the silicon detector,  $\Delta R$  between the probe jet and the tagged jet, and the invariant mass of the probe and the tagged jet. The TRF cannot be constructed explicitly as a function of  $m_{qq}$ , as we use this variable to interpolate from the sidebands into the signal region. A small  $m_{qq}$  depen-

dence of the tagging rate may result from correlations between  $m_{qq}$  and properties of the  $b$  jets that are not modeled by the TRF. The TRF is therefore further scaled by the ratio of the observed  $m_{qq}$  distribution to the predicted  $m_{qq}$  distribution in the low-mass region,  $m_{bb} < 75 \text{ GeV}/c^2$  (*tune* region in Fig. 1). The correction, a smooth function of  $m_{qq}$ , is of order 5%.

We consider three sources of systematic uncertainty on the shape of the  $Q$  distribution for the multijet background. The interpolation uncertainty accounts for possible differences in the TRF between the regions where it was measured (*tag*) and applied (*signal*). An alternative TRF is measured using events with  $25 < m_{qq} < 35 \text{ GeV}/c^2$  or  $120 < m_{qq} < 130 \text{ GeV}/c^2$  (labeled *control* in Fig. 1). The difference in the shapes of the predicted background distribution in  $Q$  for the two TRFs is treated as a systematic uncertainty. The second source is due to uncertainty in applying the  $m_{qq}$  tuning to the *signal* region. An alternative tuning is derived using events with  $m_{bb} > 170 \text{ GeV}/c^2$ , which is similarly background-dominated. Finally, we estimate a mismodeling uncertainty due to a possible limitation of the four-dimensional TRF parametrization to describe all the quantities that affect the shape of the  $Q$  distribution. In a large simulated  $t\bar{t}$  sample, we derive a TRF using events in the *signal* region and use it to predict the number of double-tagged events in the same *signal* region. The difference in the *signal* region between the  $Q$  distribution for double-tagged events and TRF-weighted single-tag events is used to derive the mismodeling uncertainty in the TRF method. This uncertainty describes any intrinsic failure of the TRF method to model  $Q$  distributions, independently of the details of the data sample.

The systematic shape uncertainties are shown in Fig. 2. In the region  $Q \gtrsim -14$ , where a majority of the Higgs

TABLE I. Number of predicted standard-model Higgs boson signal events and median expected and observed 95% confidence level upper limits on the  $VH$  production cross section, expressed as a multiple of the standard model cross section for several Higgs boson masses. A band containing 68% of simulated experiments are shown as positive and negative deviations from the median expected limit. The final column shows the observed limit on the cross section in  $pb$ .

$M_H$ (GeV/ $c^2$ )	SM $VH$ $N$	Expected limit ( $\sigma/\sigma_{SM}$ )	Observed limit ( $\sigma/\sigma_{SM}$ )	Observed limit (pb)
100	7.2	$28.6^{+12.7}_{-8.4}$	29.4	13.8
105	6.6	$33.5^{+14.8}_{-9.9}$	37.4	14.8
110	6.4	$36.1^{+15.8}_{-11.2}$	38.6	13.2
115	5.5	$37.1^{+16.3}_{-10.4}$	37.9	11.1
120	5.2	$39.7^{+16.8}_{-12.2}$	37.5	9.48
125	4.2	$47.1^{+20.2}_{-14.3}$	43.7	9.58
130	3.5	$53.6^{+22.9}_{-15.6}$	47.6	9.05
135	2.6	$80.2^{+34.6}_{-23.2}$	72.8	12.1
140	2.0	$114^{+51.7}_{-35.9}$	106	15.4
145	1.3	$176^{+81.0}_{-52.7}$	164	20.8
150	0.86	$196^{+127}_{-87.8}$	263	29.1

boson signal would be, the systematic uncertainty on the background model is smaller than a few events per bin.

Figure 3 shows the distribution of  $Q$  for a signal ( $m_H = 120 \text{ GeV}/c^2$ ), the background contributions, and the observed data. There is good agreement over the range of  $Q$  and no evidence of a  $VH$  signal.

To test for the presence of a  $VH$  signal in the data, a binned likelihood of the distribution of the data in  $Q$  is computed for the background-only and the signal + background hypotheses. The normalization of the multijet background model is a free parameter that is fit to the data. Limits on the  $VH$  cross section are extracted using the modified frequentist scheme [27].

Table I lists the expected and observed limits on the  $VH$  cross section expressed as a multiple of the SM cross section,  $\sigma_{\text{SM}}$ , for different Higgs boson masses. The observed limits agree with the expected ones. The systematic uncertainties on the background model significantly affect the sensitivity: without these, the expected limit would be 30% lower.

In summary, we report a limit on the production cross section of the standard-model Higgs boson in association with a vector boson  $V = W, Z$  with hadronic decays. Tighter limits are being obtained in the semileptonic decay channels. However, this is the first limit obtained in the difficult all-hadronic channel in run II. We expect the analysis to be refined with time, and to be able to contribute to the overall Tevatron information on light Higgs production when all data of the Tevatron run II have been analyzed.

We thank the Fermilab staff and the technical staffs of the participating institutions for their vital contributions.
