(Received 23 December 2015; revised manuscript received 18 March 2016; published 21 April 2016)

We present a theoretical analysis of the normal and superfluid fractions of quantum fluids described by a nonequilibrium extension of the Gross-Pitaevskii equation in the presence of an external potential. Both disordered and regular potentials are considered. The normal and superfluid fractions are defined by the response of the nonequilibrium quantum fluid to a vector potential, in analogy with the equilibrium case. We find that the physical meaning of these definitions breaks down out of equilibrium. The normal and superfluid fractions no longer add up to one and for some types of external potentials they can even become negative.

I. INTRODUCTION

The hydrodynamic behavior of multimode laser systems has been recognized long ago [1,2], but it is on the platform of semiconductor exciton-polaritons that a systematic investigation of the hydrodynamics of photonic systems has been performed [3]. Microcavity polaritons are hybrid light matter excitations in semiconductor heterostructures consisting of a quantum well embedded inside an optical microcavity [4]. When the optical mode is resonant with the quantum well exciton frequency, the quasiparticles are the coherent superpositions of exciton and photon. Thanks to the photonic component, the microcavity polariton is much lighter than the bare exciton, which enhances the coherence properties. Thanks to the excitonic component, polaritons show a significant interaction strength. Being bosonic particles, microcavity polaritons can show long range phase coherence in the quantum degenerate regime, giving rise to superfluid [5] properties, such as quantized vortices [6].

The photonic component also introduces losses, which makes it so far impossible to achieve fully equilibrated Bose-Einstein condensation. In order to compensate for the finite polariton lifetime, particles have to be injected. The two main schemes are resonant and nonresonant excitation. In the former regime, the velocity of the polariton fluid can be tuned by varying the angle of the excitation laser. With this pumping scheme, superfluidity according to the Landau criterion (absence of scattering off defects) [7] and the nucleation of quantized vortices [8] as well as solitons [9] have been experimentally observed. Despite the finite polariton lifetime, the observed phenomenology in those experiments was close to the equilibrium behavior.

From a conceptual viewpoint, the main disadvantage of resonant excitation is the fact that the pumping laser fixes the phase of the quantum fluid, which excludes the study of superfluidity in the sense of linear response or metastable superflow. It has been argued [3] that the most precise and quantitative definition of superfluid f_s and normal f_n fractions involves the response of the quantum gas to a weak transverse vector potential $\mathbf{A}$ as analyzed in Ref. [10]. For a spatially homogeneous system of density n , the normal fraction f_n can be defined as

$$f_n = \lim_{q \rightarrow 0} \frac{m}{n} \chi_T(\mathbf{q}). \quad (1)$$

Here m is the effective mass and $\chi_T(\mathbf{q})$ is the susceptibility tensor relating the average transverse current to the applied vector field in Fourier space.

The major question here is to what extent the nonequilibrium character of polariton condensates affects their superfluid properties. A theoretical study was performed by Keeling on the superfluid fraction of a homogeneous driven-dissipative polariton condensate with a Keldysh functional integral approach [11]. Out of equilibrium, a nonvanishing normal component is always present, due to nonequilibrium fluctuations.

The work by Janot *et al.* [12] addressed superfluidity in the disordered case. A reduction in superfluid fraction due to disorder is due to the pinning of the fluid in the potential minima and a theoretical estimate can be obtained at the mean field level [13,14]. In the theoretical study of Ref. [12], the response was studied to a small twist θ of the phase between two boundaries of the condensate separated by its size L . This is equivalent to the presence of a weak vector potential $\mathbf{A} = \mathbf{e}_x \theta / L$. As argued in Ref. [12], the superfluid stiffness in this case can be estimated in accordance with the equilibrium definitions [15,16] as

$$f_s = \frac{\omega(A) - \omega(0)}{A^2}, \quad (2)$$

where $\hbar\omega$ is the chemical potential of the condensate.

The weak vector potential $\mathbf{A} = \mathbf{e}_x \theta / L$ corresponds to a slow rotation at a velocity of less than one quantum of circulation $v < 2\pi/L$. Due to the phase quantization, the superfluid cannot rotate, so that the current is supported by the normal phase only (Hess-Fairbank effect) [5]. This allows us to define the normal fraction in terms of the dependence of the current density on the gauge field

$$f_n = \frac{\langle j_x(A_x) \rangle}{n A_x}. \quad (3)$$

The application of (synthetic) gauge fields in optical systems has developed into an active field of research [17], thanks to several experimental breakthroughs [18–20] and a wealth of theoretical proposals. Seen from this context, we address the question of the effect of a small gauge field on the frequency and current in a nonequilibrium condensate.

II. MODEL

We will apply the aforescribed definitions of f_s and f_n to the systems described by the generalized Gross-Pitaevskii equation (gGPE) [21,22], which is taken in the form [3]

$$i\hbar \frac{\partial \psi}{\partial t} = \left[-\frac{\hbar^2 \nabla^2}{2m} + g|\psi|^2 + V + \frac{i}{2} \left(\frac{P}{1 + |\psi|^2/n_s} - \gamma \right) \right] \psi, \quad (4)$$

with a static potential $V(\mathbf{r})$ and a contact interaction with the strength g . The imaginary term in the square brackets on the right-hand side describes the saturable pumping (with strength P and saturation density n_s) that compensates for the losses (γ). The physical origin of the pumping term for exciton-polariton condensates is an excitonic reservoir that is excited by a nonresonant laser.

While the field can reach in this model a stationary state, its properties are not described by equilibrium statistical physics. Equation (4) belongs to a class of models that is used in the description of pattern formation out of equilibrium [23]. The physical reason for the out of equilibrium condition of polariton condensates is the energy flux from the high energy modes that are excited by the pumping laser toward the lower polariton region.

It should be noted that we have not included the noise terms related to the fluctuations that accompany the dissipation [24]. This approximation corresponds to taking the mean field limit ($|\psi|^2 \rightarrow \infty$, while keeping $g|\psi|^2$ and $|\psi|^2/n_s$ constant). While the condensate fraction in this approximation is strictly equal to unity, this does not hold automatically for the superfluid fraction. It was shown for the equilibrium Gross-Pitaevskii equation with disorder that the mean field limit of the superfluid to Bose-glass phase boundary can be found by computing the superfluid fraction from the GPE without including any fluctuations [14].

In general, the pumping intensity P is coordinate dependent and can be represented as $P(\mathbf{r}) = P_0 p(\mathbf{r})$, with $P_0 = \max P(\mathbf{r})$. Assuming that the interaction strength is positive, $g > 0$, it is convenient to rewrite Eq. (4) in a dimensionless form, by expressing the particle density $|\psi|^2$ in units of $n_0 \equiv n_s(P_0/\gamma - 1)$, time in units of $\hbar/(gn_0)$, and length in units of $\hbar/\sqrt{2mgn_0}$:

$$i \frac{\partial \psi}{\partial t} = \left[-\nabla^2 + |\psi|^2 + V_0 v + ic \frac{1 - |\psi|^2 + (1 + v^{-1})(p - 1)}{1 + v|\psi|^2} \right] \psi. \quad (5)$$

Equation (5) contains three dimensionless scalar parameters: $V_0 = \max |V(\mathbf{r})|/gn_0$, $c = \gamma/(2gn_s)$, and $v = n_0/n_s$. The dimensionless functions $p(\mathbf{r})$ and $v(\mathbf{r}) = V(\mathbf{r})/(V_0 gn_0)$ describe the spatial distributions of the pumping intensity and static potential, respectively.

Our numerical simulations are performed for a region of sizes $L_x \times L_y$ with periodic boundary conditions in the x direction and the Neumann boundary conditions at $y = 0, L_y$. A uniform grid with $N_x \times N_y$ nodes is used. A vector potential, chosen as $\mathbf{A} = (A_x, 0, 0)$ with constant A_x , is introduced by replacing $\partial/\partial x$ with $\partial/\partial x - iA_x$ in Eq. (5). For electrically

charged particles, our configuration would correspond to a 2D cylindrical shell in an axially symmetric magnetic field parallel to the cylinder axis. We should keep in mind that in the case of an inhomogeneous static potential and/or pumping intensity, described by the functions $v(\mathbf{r})$ and $p(\mathbf{r})$, respectively, the average current $\langle j_x \rangle$ can be nonzero even at $A = 0$.

As the most natural generalization of the expression (3) for f_n to the case of nonvanishing steady state currents, we take

$$f_n = \frac{\langle j_x(A_x) \rangle - \langle j_x(0) \rangle}{nA_x}, \quad (6)$$

where the current density is given by the expression

$$\mathbf{j} = \text{Im}[\psi^* \nabla \psi]. \quad (7)$$

III. RANDOM POTENTIALS

Irregular potential landscapes are highly relevant for experimental realizations of polariton condensation because of growth imperfections in the semiconductor heterostructures. At equilibrium, the interplay between Bose-Einstein condensation and disorder gives rise to rich physics, with a zero temperature superfluid to Bose-glass quantum phase transition [25].

We consider the case of a uniform pumping intensity [$p(\mathbf{r}) = 1$] and a static potential, described by a random distribution $v(\mathbf{r})$. Two examples of the used random distributions, $v_A(x, y)$ and $v_B(x, y)$, with the correlation length $\xi_v = 5$ and 3, respectively, are shown in Figs. 1(a) and 1(b).

In Fig. 1(c) we plot the quantities f_s and f_n , corresponding to these potential distributions, as a function of the strength V_0 of the potential. In a qualitative agreement with the results of Ref. [12], for both random potentials the function f_s decreases with V_0 and falls to zero at a sufficiently strong potential. At the same time, in the whole range of V_0 under consideration, the calculated f_n remains close to zero or even becomes negative at large V_0 , so that the expected “sum rule” $f_s + f_n = 1$ is obviously violated. At first sight, this violation could be related exclusively to the calculated f_n [e.g., to lack of physical meaning of expression (6) or a lack of numerical accuracy in the corresponding estimation]. However, a deeper analysis shows that the problem actually has a more general character. Indeed, from the inset to Fig. 1(c) one can see not only a pronounced asymmetry of $f_n(A_x)$, which further illustrates inconsistencies in treating the found f_n as the normal fraction of the condensate, but also the presence of a clear discontinuity of $f_s(A_x)$ at $|A_x| \rightarrow 0$. The latter allows us to put under question also the possibility to interpret the calculated f_s as the superfluid stiffness. In other words, in the presence of a random potential, neither Eq. (2) nor Eq. (6) seem to provide correct estimates for the superfluid and normal fractions of the condensate described by Eq. (5). This fact can be attributed to the existence of nonnegligible in-plane currents in the condensates under consideration, even at $A = 0$. Below we will illustrate the above statement by few simple examples with regular potentials.

IV. REGULAR POTENTIALS

First, let us consider a structure with a partial cut in the direction perpendicular to the vector potential $\mathbf{e}_x A_x$. The cut is

FIG. 1. Distributions $v_A(x, y)$ (a) and $v_B(x, y)$ (b) for two random potentials with the correlation length $\xi_v = 5$ and 3, respectively. (c) f_s and f_n , calculated for $v = v_A$, $L_x = L_y = 64$, $N_x = N_y = 32$, $A_x = 0.1$ and for $v = v_B$, $L_x = L_y = 64$, $N_x = N_y = 64$, $A_x = 0.03$, as a function of V_0 . Inset: f_s and f_n , calculated for $v = v_A$, $L_x = L_y = 64$, $N_x = N_y = 32$, $V_0 = 0.24$, as a function of A_x . The calculations are performed for $v = 1$, $c = 1$, $p(\mathbf{r}) = 1$. (d) $1 - f_s$ and f_n , plotted as a function of c , for $v = v_B$, $L_x = L_y = 64$, $N_x = N_y = 64$, $A_x = 0.03$, $v = 1$, $p(\mathbf{r}) = 1$ and three different values of V_0 .

introduced through the additional condition $\psi|_{x=L_x/2, y \leq L_{\text{cut}}=0} = 0$. An example of the density and current distributions in a system with such a cut, as given in Figs. 2(a) and 2(b), respectively, corresponds to $V_0 = 0$, $p = 1$, $c = 1$, and $v = 2$.

At those parameter values the contribution of the pumping-loss term to gGPE is relatively large [see Eq. (5)] leading to the appearance of rather strong currents on both sides of the cut [see Fig. 2(b)]. The corresponding values of f_s and f_n as well as their sum are significantly smaller than one [see Fig. 2(c) for $v \leq 2$]. With increasing v , the role of the pumping-loss term is suppressed, Eq. (5) approaches the standard Gross-Pitaevskii equation, and the quantities f_s and f_n gradually restore their

FIG. 2. Density $|\psi|^2$ (a) and current j_x (b) distributions, calculated for a system with $L_x = L_y = 64$, $N_x = N_y = 32$, $L_{\text{cut}} = 0.4L_y$, $V_0 = 0$, $p = 1$ and $c = 1$ at $v = 2$, $A_x = 0$. (c) f_s and f_n , calculated for the same system at $A_x = 0.05$, as a function of v .

physical meaning, so that the sum $f_s + f_n$ tends to reach 1 at $v \sim 10$.

In Fig. 3 we show $f_s(V_0)$ and $f_n(V_0)$ calculated for a system, where the aforementioned cut is replaced with a potential well $V_0 v(x)$, uniform in the y direction (see the inset to Fig. 3). Figure 3 corresponds to a relatively large value of the parameter c ($c = 3$). In this case, the behavior of $f_n(V_0)$ closely resembles that in the presence of a random static potential [Fig. 1(c)]. The quantity $f_s(V_0)$, shown in Fig. 3, first manifests a decrease, qualitatively similar to that in Fig. 1(c). At larger V_0 , this

FIG. 3. f_s and f_n as a function of V_0 for $L_x = 26$, $N_x = 128$, $c = 3$, $v = 2$, $p = 1$, $A_x = 0.04$. Inset: Shape $v(x)$ of the static potential (solid line) and density distribution $|\psi(x)|^2$ at $V_0 = 0.45$ (dashed line).

FIG. 4. f_s (a) and f_n (b) as a function of V_0 for $L_x = 26$, $N_x = 128$, $\nu = 2$, $p = 1$, $A_x = 0.04$ and different c . Inset: $f_s + f_n$ as a function of V_0 .

decrease is overridden by oscillations of $f_s(V_0)$. Here the definition (1) clearly loses its physical meaning of normal fraction.

The equality $f_s + f_n = 1$ is seen to be satisfied only at $V_0 \rightarrow 0$. Like in our previous example, when suppressing the pumping-loss term (in the present case this is realized by decreasing the parameter c) so that the system approaches an equilibrium regime, the behavior of $f_s(V_0)$ and $f_n(V_0)$ becomes more reasonable (see Fig. 4). In particular, as seen from the inset to Fig. 4, the range of potential strengths V_0 , where the condition $f_s + f_n = 1$ is obeyed, increases clearly with decreasing c , so that at $c = 0.03$ this range includes $V_0 \sim 1$. Qualitatively similar results are obtained in the case of a random potential: at sufficiently small c the values of f_s and f_n always lie within the physically meaningful interval (0,1) and their sum tends to 1 [see Fig. 1(d)].

In our last example we consider a system where a strong asymmetry is induced by an inhomogeneous pumping with the intensity maximum shifted with respect to the extrema of the potential $V_0 v(x)$ [see Fig. 5(a)]. The system is uniform in the y direction. As displayed in Fig. 5(b), the combined effect of the potential barrier and inhomogeneous pumping leads to a very nonuniform density distribution with strong currents, mainly in the positive x direction. In Fig. 5(c), at relatively small V_0 , reasonable, nearly zero values of f_s are accompanied by a counterintuitive decrease of f_n with increasing the height V_0 of the potential barrier. At larger V_0 , both $f_s(V_0)$ and $f_n(V_0)$ demonstrate some oscillatory behavior, which can hardly have any physical meaning. One can also notice that the condition

FIG. 5. (a) Functions $v(x)$ (solid line) and $p(x)$ (dashed line), which determine the spatial distributions of the static potential and the pumping intensity, respectively, in a periodic system with $L_x = 55$, $N_x = 128$. (b) Distributions of the density $|\psi|^2$ (dotted line) and current density j_x (dash-dotted line) at $\nu = 3$, $c = 4$, and $V_0 = 3.3$. (c) f_s and f_n , calculated for $\nu = 3$, $c = 4$, $A_x = 0.035$, as a function of V_0 . (d) and (e) f_s and f_n , respectively, as a function of A_x for $\nu = 3$, $c = 4$ and three different V_0 .

$f_s + f_n = 1$ is not fully satisfied even at $V_0 = 0$. As seen from Fig. 5(d), at sufficiently large V_0 , the calculated function of $f_s(A_x)$ can have a pronounced discontinuity at $|A_x| \rightarrow 0$, which is similar to that shown in the inset to Fig. 1(c) for the case of a random static potential. The origin of this discontinuity can be qualitatively understood by associating the presence of a nonzero average current in the system at $A_x = 0$ with an effective vector potential $A_{0x} \neq 0$. Then, assuming like before that the chemical potential of the superfluid is proportional to the vector potential squared, $\omega(A) = \alpha A^2$, one obtains from Eq. (2) the expression $f_s = (1 + 2A_{0x}/A_x)\alpha$, which obviously diverges at $|A_x| \rightarrow 0$. The existence of a nonzero average current in the absence of an externally applied vector potential seems to be responsible also for the asymmetry of the calculated function $f_n(A_x)$ at large V_0 , both in the present example [see Fig. 5(e)] and in the case of a random potential [see the inset in Fig. 1(c)].

V. CONCLUSIONS

Summarizing our numerical findings, we can conclude that the definitions (1) and (2) lose their physical interpretation in terms of normal and superfluid fractions in the presence of driving and decay. For what concerns the definition of the superfluid fraction (2), this may not be that surprising, since the stationary state is no longer the one with minimal (free) energy. For the case of a disordered potential, however, the superfluid fraction shows an expected behavior as a function of disorder strength, starting from one at zero disorder and falling to zero for stronger disorder.

For other potential profiles however, such as a single potential dip, the equilibrium definition of the superfluid fraction becomes problematic. It becomes negative for certain values of the potential. This means the frequency of the condensate shows a decrease instead of an increase under the application of a phase twist in the boundary condition. In equilibrium, this is forbidden, since time-reversal invariance guarantees that the condensate wave function in the ground state is real. Out of equilibrium, where time-reversal invariance is broken, the steady state also has currents for periodic boundary conditions. The interplay between this existing current and the applied phase twist can then lead to a lower frequency. In the case of a spatially inhomogeneous pump, the behavior of the superfluid fraction even differs more dramatically from the equilibrium one, showing large oscillations as function of the external potential strength [see Fig. 5(c)].

At first, the definition of the normal fraction, based on the current response of the system, could be thought to be more robust with respect to the nonequilibrium condition. Our numerical analysis however strongly contradicts this.

Already in the case of the disordered potential, where the superfluid fraction behaves reasonably, the normal fraction does not show the expected behavior. We also attribute the failure of the equilibrium definition of the superfluid fraction to the presence of currents in the steady state. These currents invalidate the physical picture that the current response is due to a limited stiffness of the condensate phase. When currents are present in the steady state, also a redistribution of the density will contribute to the current response. The interplay between the density redistribution and the steady state currents can then even lead to negative normal fraction, as we observed in the case of the disordered potential landscape [Fig. 1(c)]. The conclusion of our numerical findings is negative: the equilibrium definitions for superfluid and normal fractions no longer give meaningful results out of equilibrium in the presence of external potentials that induce currents.

It will be of interest to include the effect of fluctuations in the calculation of the superfluid and normal fractions. Within the classical field formalism, this could be done in the truncated Wigner approximation [24]. Of specific interest are the superfluid and normal fraction close to the phase transition. At equilibrium, it is of the BKT type in two dimensions, with a characteristic jump in the superfluid fraction. Indications that the BKT character of the phase transition is preserved out of equilibrium were found recently in numerical simulations in the parametric oscillation regime [26], but the behavior of the normal and superfluid fractions has not been addressed yet.
