30 **Abstract:** Superstructures with nanoscale building blocks, when coupled with the precise control
31 of the constituent units, open opportunities in rationally designing and manufacturing desired
32 functional materials. Yet, synthetic strategies for the large-scale production of superstructures are
33 scarce. We report a scalable and generalized approach to synthesizing superstructures assembled
34 from atomically precise $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ and other rare earth metal oxide nanoclusters alongside a
35 detailed description of the self-assembly mechanism. Combining operando small angle X-ray
36 scattering, ex-situ molecular and structural characterizations, and molecular dynamics simulations
37 indicates that a high-temperature ligand switching mechanism, from oleate to benzoate, governs
38 the formation of the nanocluster assembly. The chemical tuning of surface ligands controls
39 superstructure disassembly and reassembly, and furthermore, enables the synthesis of multi-
40 component superstructures. This synthetic approach, and the accurate mechanistic understanding,
41 are promising for the preparation of superstructures for use in electronics, plasmonics, magnetics
42 and catalysis.

43

44

45

46 **Introduction**

47 The assembly of nanoparticles into superstructures (also called superlattices) is a promising
48 route towards the synthesis of novel materials with properties from the collective interactions of
49 the assembled components^{1,2}. Such cross-scale orderings, coupled with the precise control of each
50 constituent nanoparticle's physical dimensions and chemical composition, hold promise for
51 emergent opportunities in electronics³⁻⁶, plasmonics⁷⁻¹⁰, magnetics¹¹⁻¹⁴, and catalysis¹⁵⁻¹⁹.
52 Typically, the synthesis of nanoparticle superstructures relies on a dedicated control of interparticle
53 attraction/repulsion (for example, van der Waals forces, electrostatic forces, hydrogen bonding,
54 solvent interactions, and steric forces) to minimize disordered aggregates²⁰, which can be achieved
55 by the incorporation of surface directing domains^{21,22}, such as in DNA- or polymer-guided
56 assembly^{7,23-25}, through solvent depletion interactions²⁶, or through slow solvent evaporation
57 processes²⁷⁻³⁰. Despite substantial progress, established superstructure synthetic methods remain
58 low in yield and scalability. More importantly, assembly mechanisms are generally unknown,
59 limiting our ability to rationally design superstructures. This is, in large part, due to the inaccurately
60 defined building blocks (i.e. uniform in nanoscale size but lack atomic level precision) and the
61 associated complexity of interparticle interactions.

62 Here, we report a large-scale, one-pot colloidal synthesis of superstructures comprised of
63 atomically precise $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ (Ceria) and other rare earth metal nanoclusters, which informs
64 an unprecedentedly detailed description of the self-assembly mechanism through a high-
65 temperature ligand switching surface chemistry. Using *operando* small angle X-ray scattering
66 (SAXS), a powerful technique capable of providing information about both superstructure
67 ordering³¹ and nanoparticle structure³², in combination with *ex-situ* solid state nuclear magnetic
68 resonance (SSNMR) and single crystal X-ray diffraction (SCXRD), we fully mapped the

69 nanocluster nucleation and assembly pathways. As illustrated in **Fig. 1**, we identified a temperature
70 (T)-dependent surface ligand switching phenomenon, from oleate (OA) to benzoate (BA), over
71 $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ building blocks that leads to formation of superstructures. Molecular dynamics (MD)
72 simulations validated the favourable energetics of ligand switching at high temperature and the
73 pivotal role that BA π -stacking interactions play in governing the superstructure generation. This
74 strategy is applicable to a broad range of rare earth metal oxide nanocluster superstructures and
75 enables the control of superstructure disassembly/reassembly through surface ligand chemistry.
76 By utilizing different nanocluster building units, we have created multi-component superstructures
77 and even high-entropy alloy analogous superstructures (HEAAS).

78 **Results and Discussion**

79 **Ceria nanocluster superstructure synthesis and *operando* SAXS**

80 Ceria superstructures were generated through a colloidal synthesis from cerium acetate
81 refluxing in a benzyl ether solvent (20 mL) with a small amount of oleic acid for 4 hours at 290 °C.
82 The product is a gray solid precipitate (**Supplementary Figure 1a, b**) and remains structurally
83 stable in hexanes and isopropanol solvents. They can be readily generated on a gram scale (~4.3
84 g) in a single, scaled reaction using 400 mL of solvent (**Supplementary Figure 1c**). **Fig. 2a-c** and
85 **Supplementary Figure 2** show the representative high-angle annular dark-field scanning
86 transmission electron microscopy (HAADF-STEM) images of the as-synthesized ceria
87 superstructures. Rod-like structures are observed on the order of 1–4 μm long and 30–100 nm
88 across. These structures are comprised of a superlattice of monodisperse 1.4 ± 0.3 nm ceria
89 nanoclusters.

90 *Operando* SAXS measurements were performed (**Fig. 2d-e**) to access details of the
91 superstructure and its formation pathway. These experiments were conducted using synchrotron

92 hard X-rays and a specialized reactor (**Supplementary Figure 3a, b**) similar to that used in a
93 previous study³¹. SAXS profile monitoring at $T = 135 - 290$ °C along the reaction show evolution
94 of a shoulder peak at $q = 0.2 \text{ \AA}^{-1}$ emerging at 260 °C (**Fig. 2d**). This feature becomes more
95 pronounced at 290 °C and fits well with a hard sphere model having a radius of 0.89 nm
96 (**Supplementary Figure 3c**). Therefore, nanoclusters are formed in the initial stages of the
97 reaction without the structure peaks associated with superstructures being observed. Allowing
98 further reaction, a series of time (t)-dependent SAXS profiles is presented in **Fig. 2e** with the $t = 0$
99 min measurement occurring upon the reaction temperature reaching 290 °C. Long-range structure
100 peaks (**Fig. 2e** and **Supplementary Figure 3d**) start to appear at 25 min and increase in intensity
101 as the reaction progresses. These are accompanied by a large rise in the low q region associated
102 with the scattering from the superstructures. The structure peaks are assigned to a body-centered
103 tetragonal (*bct*) assembly (lattice parameters: $a = 1.9$ nm and $b = c = 3.3$ nm) with peak indices
104 labeled in **Fig. 2e**. Some peaks are unobservable above the background (such as (022) or (121))
105 due to the 1D shape of the superstructure. Clearly, the superstructures form only at 290 °C,
106 independently from the nanocluster generation which occurs at lower temperatures.

107 **OA-to-BA ligand switching for superstructure formation**

108 We found that benzyl ether solvent is critical to the formation of these assemblies. Attempting
109 this synthesis in alternate solvents such as 1-octadecene, dioctyl ether, or diphenyl ether does not
110 generate superstructures. Previously, the decomposition of benzyl ether into benzaldehyde and BA
111 has been implicated in the shape variations of magnetite (Fe_3O_4) nanocrystals³³. ¹H NMR analyses
112 of benzyl ether heated to 290 °C show that this system also experiences a steady increase of
113 benzaldehyde over time (**Supplementary Figure 4a, b**). Moreover, injecting neat, excess
114 benzaldehyde (0.75 mL) to the synthesis at 290 °C reduces the reaction time by a factor of 4 to

115 yield the same superstructures. Benzaldehyde has previously been suggested as a source of BA
116 ligands catalyzed by reaction with benzyl alcohol on yttrium oxides to yield lamellar assemblies³⁴.
117 Other metal oxides can also catalyze the Cannizzaro reaction to convert benzaldehyde to BA and
118 benzyl alcohol³⁵. We envision that, through similar means (**Supplementary Figure 5a, b**), BA is
119 likely to form on and strongly bind to ceria nanoclusters to induce the formation of superstructures.

120 $^{13}\text{C}\{^1\text{H}\}$ cross polarization magic angle spinning (CPMAS) SSNMR was used to reveal the
121 surface ligands of nanoclusters and superstructures. The samples collected from different reaction
122 stages were purified and dried in vacuum prior to analysis. As displayed in **Fig. 2f**, nanoclusters
123 isolated before superstructure formation (290 °C, t = 0 min) exhibited two major resonances around
124 130 ppm, typical of sp^2 hybridized C, and 40 ppm from sp^3 hybridized C. When measurement is
125 taken for the superstructure solid, the peak near 40 ppm is significantly diminished. The sp^3
126 contribution is assigned to OA ligands and is thought to be completely replaced by BA in the
127 superstructure. The broad linewidths of the resonances are assigned to the presence of
128 paramagnetic Ce^{3+} centers (Ce^{3+} is discussed below)³⁶. When $^{13}\text{C}_1$ -labeled OA is used in the
129 synthesis, OA remained undetectable in the superstructure solid, further confirming the extent of
130 replacement. Raman spectroscopy performed on the dried superstructure confirms the presence of
131 BA as surface ligands (**Supplementary Figure 5c and Supplementary Table 1**)³⁷.
132 Characterization of the superstructure dispersion in solution phase by ^1H NMR (**Supplementary**
133 **Figure 6a**) provides further evidence of BA with resonances at 8.15 ppm, 7.68 ppm, and 7.52 ppm.
134 Benzaldehyde, on the other hand, is not observed in the superstructure as is evident from the
135 absence of a resonance at 7.88 ppm (**Supplementary Figure 6b**).

136 The superstructure can be dissolved to disperse the nanoclusters in non-polar solvents (such as
137 hexanes) at room temperature by adding excess oleic acid, yielding a golden-brown dispersion

138 (Supplementary Figure 7a, b) that has a reduced absorbance of visible light compared to the
139 assembled structures in UV-Vis analysis (Supplementary Figure 8). Correspondingly,
140 disassembled nanoclusters can be seen in transmission electron microscopy (TEM) images
141 (Supplementary Figure 7b) and are associated with the return of the OA sp^3 C signal in the ^{13}C
142 SSNMR spectra (Fig. 2f). As such, surface BA ligands can be reversibly exchanged with OA to
143 disassemble the superstructure. Disassembly can also be achieved using more polar solvents in the
144 absence of OA, including pyridine, dichloromethane, and dimethylformamide (DMF), which are
145 able to better solvate the BA-capped particles.

146 Surprisingly, using a pyridine ceria nanocluster solution disassembled from superstructures,
147 we were able to obtain single crystals of the nanoclusters following the addition of acetonitrile and
148 water. It is worth mentioning that the amount of acetonitrile needs to be carefully controlled to
149 permit a slow crystal nucleation and growth over the course of several weeks; an excess of
150 acetonitrile results in disordered aggregates. SCXRD results show a monoclinic $P2_1/n$ structure
151 (Fig. 2g and Supplementary Figure 9) (lattice parameters: $a = 2.13$ nm, $b = 2.51$ nm, $c = 2.55$
152 nm, and $\beta = 92.02^\circ$) is obtained with $Ce_{24}O_{28}(OH)_8$ nanocluster building blocks, similar to the one
153 previously reported^{38,39}. The size of the $Ce_{24}O_{28}(OH)_8$ is 1.53 nm x 1.46 nm x 1.21 nm. This
154 matches well with the clusters observed in the TEM images (Fig. 2a-c). In addition, the parameters
155 of the single crystal also resemble the body-centered tetragonal superlattice determined by SAXS,
156 indicating a similar packing strategy in the single crystals as well as the superstructures. As
157 illustrated in Fig. 2g and Supplementary Figure 11, each $Ce_{24}O_{28}(OH)_8$ nanocluster contains 2
158 Ce^{3+} and is ligated by 30 BA and 8 pyridines. These pyridines consist of 4 OH-bound (via H-
159 bonding) and 4 Ce-bound species (Supplementary Figure 10). Given that the pyridine is only
160 introduced to disassemble the superstructure for single crystal growth, the SCXRD result allows

161 us to further confirm that the building units in the superstructures are indeed atomically precise
162 $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ units with the sole packing ligand of 30 BAs.

163 Matrix-assisted laser desorption/ionization-time of flight mass spectrometry (MALDI-TOF
164 MS) was also used to characterize the disassembled ceria nanoclusters. Disassembling the
165 superstructures in DMF and combining with an anthracene matrix, the MALDI-TOF MS spectrum
166 in **Supplementary Figure 11** was collected. The first major spectral peak appears at 4061 m/z,
167 which can be best assigned to $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8(\text{BA})_1$ (theoretical m/z is 4068), and these peaks
168 primarily repeat at the interval of 121 m/z. The difference of 121 m/z corresponds to different BA
169 coverages. These peaks are further subdivided by units of 16 m/z, corresponding to changes in the
170 number of O atoms in the cluster, and have varying intensities that lead to the 105 m/z separations
171 in some of the peak maxima. The peaks terminate before the calculated maximum mass of 7580
172 m/z for $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8(\text{BA})_{30}$. Clearly, the cluster is disintegrated by the laser in MALDI-TOF MS
173 measurement (which is common for ionic clusters in MALDI-TOF MS measurement), but the
174 result provides atomically precise characteristics of nanoclusters with BA ligands.

175 Succinctly summarized, OA-capped nanoclusters are first formed at 260 °C in the colloidal
176 synthesis, and subsequently react with benzaldehyde to induce a full ligand-switching to BA at
177 290 °C. The high temperature reaction is required to provide benzaldehyde species through the
178 thermal decomposition of benzyl ether solvent. The resultant BA-packed $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$
179 nanoclusters serve as building blocks to construct the superstructure solids.

180 **MD simulations**

181 We carried out MD simulations to understand the cross-cluster interactions that drive the
182 superstructure formation. Two models, OA-packed and BA-packed nanoclusters, were constructed

183 to mimic the reaction condition (**Fig. 3a, b**). Based on experimental observations, each model
184 contains 2 Ce₂₄O₂₈(OH)₈ nanocluster building blocks with 60 BAs, 60 OAs, and 120 benzyl ethers,
185 where the BAs in the OA-packed model and the OAs in the BA-packed model were protonated
186 (labeled as pBA and pOA) to prevent their binding to nanoclusters and to retain neutrality of the
187 system in the ligand switching. Interestingly, the BA-capped clusters spontaneously aggregate
188 independent of their initial spacing, with the final distance between two nanoclusters becoming
189 close to that of the single crystal structure, ~2.1 nm (**Fig. 3c**). In comparison, the cluster-cluster
190 distance is > 3 nm for the OA-packed one, corresponding to the dispersed form in the nanocluster
191 solution. Moreover, the BA-packed system is energetically more favorable than the OA
192 counterpart by over 100 kcal mol⁻¹ (**Fig. 3d**), which agrees with the observed OA-to-BA switching
193 in the experiment. This energy difference is attributed mainly to improvements in the van der
194 Waals or hydrophobic interactions (**Supplementary Figure 12 a,b**), probably dominated by π - π
195 interactions between adjacent BAs. The BA aromatic ring on the nanocluster surface can form
196 edge-to-face or offset stacked π - π interactions depending on the position (**Fig. 3 e,f**), providing the
197 additional energy gain that drives the self-assembly.

198 The *operando* SAXS result presents slightly different cell parameters ($a = 1.9$ nm and $b = c =$
199 3.3 nm) for the superstructure in solution phase, compared to those of the single crystal derived
200 from SCXRD ($a = 2.13$ nm, $b = 2.51$ nm, $c = 2.55$ nm, and $\beta = 92.02^\circ$). Although both structures
201 are similar, the cell volume of the superstructure (20.7 nm³) is larger than single crystal (13.6 nm³).
202 The single crystal unit cell volume can be computationally matched upon the addition of 34 BAs
203 on each nanocluster, simulating 30 BAs and the 8 Ce-bound pyridines deciphered from SCXRD
204 (**Fig. 4a**). The larger volume of the superstructure unit cell requires an even greater number (> 42)
205 of bound BA, which is impossible for small nanoclusters with limited surface area. Such a

206 deviation is likely caused by the incorporation of non-binding benzyl ether in the superstructure in
207 the solution phase. To confirm this, we calculated the cell volume as a function of the number of
208 benzyl ethers incorporated (**Fig. 4b**), where the systems were considered to contain 60 BAs (30
209 BAs per nanocluster). Our computation demonstrates that the cell volume matches well to the
210 experimental result, $\sim 20.7 \text{ nm}^3$, when 16 benzyl ethers were included (**Fig. 4c**).

211 Thermogravimetric (TGA) analysis (**Supplementary Figure 13**) was used to measure the
212 organic components of the ceria assemblies and verify that extra benzyl ether is included. It is
213 assumed that the initial structures contain $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ clusters with 30 BA ligands according to
214 SCXRD result and to maintain cluster charge neutrality and that, in the high O_2 , high temperature
215 TGA experiment, the final structures are fully oxidized to $\text{Ce}_{24}\text{O}_{48}$. It is also assumed that the first
216 5.1% of weight loss is from residual solvent. Based on the unaccounted mass, we calculate that
217 7.8 benzyl ethers per cluster are required to make up the balance, which aligns well with MD
218 simulation. These results suggest that the self-assembled ceria superstructure in the solution phase
219 contains 30 BAs and ~ 8 benzyl ethers per nanocluster in the unit cell (**Fig. 4c**).

220 The ceria nanocluster has (100) and (111) facets (**Fig. 4d**). O anions bonded to the central Ce
221 of the hexagonal (111) facet repels BA, leaving an open facet. This facet, in the single crystal,
222 binds the 4 Ce-bound pyridine ligands. The lack of pyridine in the superstructure, plus the presence
223 of benzyl ether, leads to an altered unit cell relative to the single crystal. Furthermore, our MD
224 simulations show that benzyl ether molecules surround the BA-packed nanoclusters across the yz
225 plane (**Fig. 4c**), filling the space between the nanoclusters, while the nanoclusters connect
226 periodically along the x axis with no incorporation of benzyl ether. It is along the x direction where
227 the (111) facets face one another at an offset, allowing compact packing where one BA bound to

228 the edge of the (111) facet into fits the space above the center of the hexagon in the next cell (**Fig.**
229 **4e**), while the BAs of the edges contribute to the π - π interactions that stabilize the structure.

230 **General synthesis of mono- and multi-element superstructures**

231 This superstructure synthesis can be extended to many other rare earth metal oxides, including
232 La, Sm, Eu, Gd, Tb, Ho, Er, Tm, and Yb (**Fig. 5 a-h**). Generally, their nanoclusters and
233 superstructures resemble the ceria system with slight variations in superstructure macro-shape.
234 These structures are also slower to form assemblies. Using LaO_x as an example for the non-Ce
235 lanthanides, *operando* SAXS (**Fig. 5i**) showed that ordering is not observed until 110 minutes into
236 the reaction. As with ceria, a rise in the low q region ($< 0.05 \text{ \AA}^{-1}$) is observed with the onset of a
237 structure peak ($q = 0.407 \text{ \AA}^{-1}$). For LaO_x , this peak shows a 10 times greater full width at half
238 maximum, and only one peak is evident, showing that this structure has more variability than the
239 ceria. Since the ordering in the TEM images appears similar, this may be consistent with another
240 *bct* type structure with parameters of 1.8 nm x 3.0 nm x 3.0 nm, but further corroborating evidence
241 is required to confirm this structure. Another difference from the ceria superstructures is that these
242 superstructures range from light brown to bright white rather than grey (**Supplementary Figure**
243 **14**). Like ceria, they can be disassembled in different solvents or via the addition of excess OA,
244 and they have a reduced interaction with visible light (UV-Vis spectra of SmO_x and LaO_x are
245 shown in **Supplementary Figure 15**). Unlike ceria with a dominant Ce +4 oxidation state, these
246 other elements exist primarily in their +3 oxidation state as indicated by X-ray photoelectron
247 spectroscopy (XPS) (**Supplementary Figure 16**), which is typical for non-Ce rare earth metal
248 oxides.

249

250 An interesting feature of these superstructures is that the OA-capped disassembled
251 nanoclusters can be purified and reacted in benzyl ether at 290 °C again to regenerate
252 superstructures (**Supplementary Figure 17a,b**). The ability to disassemble and reassemble
253 nanoclusters offers the opportunity to synthesize multi-component superstructures. As a proof-of-
254 the-concept example, the CeO_x, LaO_x, and SmO_x superstructures were disassembled, and their
255 nanocluster mixtures in benzyl ether were reacted to re-assemble. **Fig. 6a-f** display the low-
256 magnification and high-magnification TEM images of the binary and ternary superstructures,
257 confirming the efficacy of this strategy. Energy-dispersive X-ray spectroscopy (EDS) elemental
258 mapping confirms the uniform distribution of Ce, La and Sm elements in the ternary
259 superstructures (**Fig. 4g, h**). Two factors are thought to benefit the assembly of multi-component
260 superstructures. First, the building blocks possess a similar size (~1.4 nm), regardless of their
261 chemical composition. Second, the presence of benzyl ether in the superstructures enables local
262 structural variations that compensate for the variations in the building block structures. Such size-
263 determined binary assemblies were previously reported in the case of larger nanoparticles⁴⁰;
264 however, this is, to the best of our knowledge, the first such demonstration in the case of
265 nanoclusters. More excitingly, we created a HEAAS using La, Eu, Sm, Yb, and Ce in this method,
266 as shown in **Supplementary Figure 15c-e**. HEA is an emerging alloying strategy that involves 5+
267 elements in high concentration with high-entropy atomic disordering^{41,42}. Our HEAAS presents a
268 similar high-entropy state at a distinct length-scale, in which multiple nanoclusters serve as
269 building blocks and are randomly distributed in superstructures.

270 **Conclusion**

271 Our experimental and computational studies demonstrate that a high-temperature ligand-
272 switching mechanism governs assembly of atomically precise nanoclusters into superstructures.

273 The chemical insight presented here enables a generalized approach to synthesizing large-scale
274 nanocluster superstructures for a wide range of rare earth metal oxides and their multi-component
275 combinations. This unique synthetic capability may enable opportunities in studying how
276 superstructure physical properties originate from well-defined building units or multi-component
277 synergies in ordered structures.

278

279 **Materials and Methods**

280 **Chemicals.** Cerium acetate hydrate ($\text{Ce}(\text{Ac})_3 \cdot x\text{H}_2\text{O}$, 99.9%) and lanthanum acetate hydrate
281 ($\text{La}(\text{Ac})_3 \cdot x\text{H}_2\text{O}$, 99.9%) were purchased from STREM Chemicals Inc. Ytterbium acetate
282 tetrahydrate ($\text{Yb}(\text{Ac})_3 \cdot 3\text{H}_2\text{O}$, 99.9 %) was purchased from Accela. Europium acetate hydrate
283 ($\text{Eu}(\text{Ac})_3 \cdot x\text{H}_2\text{O}$, 99.9%), holmium acetate hydrate ($\text{Ho}(\text{Ac})_3 \cdot x\text{H}_2\text{O}$, 99.9%), thulium acetate
284 hydrate ($\text{Tm}(\text{Ac})_3 \cdot x\text{H}_2\text{O}$, 99.9%), samarium acetate hydrate ($\text{Sm}(\text{Ac})_3 \cdot x\text{H}_2\text{O}$, 99.9%) erbium
285 acetate tetrahydrate ($\text{Er}(\text{Ac})_3 \cdot 4\text{H}_2\text{O}$, 99.9%), and gadolinium acetate hydrate ($\text{Gd}(\text{Ac})_3 \cdot x\text{H}_2\text{O}$,
286 99.9%) were purchased from Alfa Aesar. Isopropanol (IPA, Certified ACS Plus), hexanes
287 (Certified ACS), acetonitrile (Certified ACS), and pyridine (Certified ACS) were purchased from
288 Fisher Chemical. Benzyl ether (99%) was purchased from Acros Chemical. Oleic acid (OAc,
289 technical grade 90%) and benzaldehyde (Reagent Plus 99%) were purchased from Sigma Aldrich.
290 ^{13}C labelled oleic acid ($1\text{-}^{13}\text{C}$, 99%) was purchased from Cambridge Isotope Laboratories, Inc. All
291 chemicals were used without further purification.

292 **Superstructure synthesis.** Nanocluster superstructures were synthesized colloiddally in a one pot
293 synthesis of 0.5 mmol of the corresponding rare earth acetate in 20 mL of benzyl ether and 0.23
294 mL of OAc. The reaction mixture was heated to 150 °C for 1 hour under flowing N_2 to purge water
295 and other impurities. Then, the reaction was heated to 290 °C, at which point the reaction mixture
296 will reflux. The reaction was held at this temperature for at least 4 hours. The reaction mixture
297 transforms from golden brown to a milky yellow color (Ce) or brown (other rare earth metals)
298 when complete. After cooling to room temperature, the product was washed via centrifugation
299 with IPA and dispersed in hexane at least twice. Washed samples manifest as a grey (Ce), white,
300 or brown (other rare earth metals) dispersion and gently settle to the bottom. This procedure was
301 repeated, scaling to 10 mmol of metal salt precursor without complication. The CeO_x reaction rate

302 was increased by introducing 0.75 mL of benzaldehyde once the reaction temperature reached 290
303 °C. This reaction was finished after 1 hour rather than 4 hours.

304 **Superstructure (dis/re)assembly and multielement assembly.** The purified superstructures
305 could be disassembled by introducing 3 mL of OAc to the hexane dispersed sample. Generally,
306 this was carried out over a few minutes. The disassembled particles were washed with acetone and
307 redispersed in hexane. These particles could be reintroduced to 20 ml of benzyl ether and rerun
308 through the above superstructure synthesis procedure to regenerate superstructures. By mixing
309 nanoclusters that were disassembled and purified, binary, and ternary mixes of CeO_x, LaO_x, and
310 SmO_x were generated. In these samples, the weights of the added metal oxides were kept equal. A
311 quinary, HEAAS was also produced using available YbO_x, CeO_x, SmO_x, EuO_x, and LaO_x. The
312 ratio of the precursors used for the quinary sample was approximately 1:1:1.5:2:2.

313 **SAXS measurements.** *Operando* SAXS measurements were executed in a specialized reactor as
314 reported by Tassone *et al.*³¹ (**Supplementary Figure 3a, b**). The reactions were carried out as
315 described earlier but scaled to the 10 mL to accommodate the smaller reactor. Measurements were
316 performed at beam 12-ID-B of the Advanced Photon Source at Argonne National Laboratory. The
317 X-ray wavelength, λ , was set to 0.886 Å. Scattered X-ray intensities were measured with a Pilatus
318 2M detector (DECTRIS Ltd). The distance from sample to detector is 2 m. Each measurement is
319 an average of 10 exposures of 0.5 s each and occurred at intervals of 60 s. 1D SAXS curves were
320 generated by averaging the 2D images azimuthally, performing a solid angle correction, and
321 normalizing to the unimpeded transmitted X-ray beam in the Irena software package developed at
322 beamline 12-ID-B. The 1D SAXS curves were fit in the SasView package
323 (<http://www.sasview.org/>) to a spherical model.

324 **NMR measurements.** ^1H NMR spectra were recorded using a Bruker AV800 spectrometer. All
325 SSNMR experiments were performed using an Agilent DD2 400 MHz NMR spectrometer
326 equipped with a Chemagnetics 3.2 mm MAS probe. ^{13}C MAS spectra were acquired both using
327 cross-polarization (CP) as well as using a Bloch decay sequence. The Bloch decay experiment is
328 expected to be better quantitative while the CP experiment accentuates the solid components of
329 the mixture. All hard pulses used 100 kHz RF power for both the Bloch decay and CP experiments
330 while CP was achieved using a 2 ms contact time. In all cases a total of 1024 scans were
331 accumulated, with the recycle delay set to 2 s and 4 s for the CP and Bloch decay experiments,
332 respectively.

333 **MALDI-TOF MS.** MALDI-TOF MS was performed on a Bruker Ultraflex III MALDI-TOF mass
334 spectrometer. Assembled structures were disassembled in DMF (10 mg mL⁻¹) and combined with
335 10 mg mL⁻¹ anthracene matrix in DMF in a 1:1 v/v ratio. The solution (0.8 μL) was dried on a
336 stainless-steel MALDI target plate two times. Calibration of the instrument in the 4 – 20 kDa range
337 was performed with a mixture of insulin, cytochrome, myoglobin, and ubiquitin.

338 **UV-Vis Measurements.** Assembled structures were dispersed in hexanes with and without oleic
339 acid in a 1 cm path length quartz cuvette for absorbance measurements. A Shimadzu UV-2600
340 spectrophotometer was used for these measurements. Each sample was measured against a
341 background of pure hexanes.

342 **TGA Analysis.** Organic component percentage was studied on a Discovery TGA5500
343 thermogravimetric analyzer (TA Instruments). Samples were prepared by centrifugation and air
344 drying. The samples were heated from room temperature to 700 °C at a ramp rate of 10 °C min⁻¹
345 in air to fully pyrolyze organic and volatile components.

346 **SCXRD.** The superstructures were washed with IPA and dispersed in minimal pyridine to yield a
347 transparent, golden solution. This solution was filtered through a 0.45 μm syringe filter. 1% DI
348 water and 2 equivalents of acetonitrile were added to the solution. Crystals were formed after
349 sitting at least 4 weeks undisturbed. Single crystals of the ceria nanoclusters were coated with
350 Paratone oil on a MiTeGen Microloop sample holder. The X-ray intensity data were measured on
351 Bruker D8 Venture Kappa four-circle diffractometer system equipped with an Incoatec I μ S 3.0
352 micro-focus sealed X-ray tube (Cu K α , $\lambda = 1.54178 \text{ \AA}$) and a HELIOS EF double bounce
353 multilayer mirror monochromator. The frames were integrated with the Bruker SAINT software
354 package using a narrow-frame algorithm. The Multi-Scan method (SADABS) was used to correct
355 for absorption effects. Structure solutions were refined in the Bruker SHELXTL Software
356 Package⁴³ within APEX and OLEX2⁴⁴. Non-hydrogen atoms were refined anisotropically and
357 hydrogen atoms were placed in geometrically calculated positions with $U_{\text{iso}} = 1.2 U_{\text{equiv}}$ of the
358 parent atom. The relative occupancy of each set of disordered atoms was freely refined. Constraints
359 and restraints were used on the anisotropic displacement parameters and bond lengths of the
360 disordered atoms. Additional solvent located in the crystal lattice was severely disordered and
361 could not be adequately modeled with or without restraints. Thus, the structure factors were
362 modified using the PLATON SQUEEZE technique, in order to produce a “solvate-free” structure
363 factor set. PLATON reported a total electron density of 225 e^- and total solvent accessible volume
364 of 1152 \AA^3 .

365 **Theoretical calculations.** The formation and structures of $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ nanocluster
366 superstructures were studied using MD simulations. The $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ nanocluster was
367 constructed based on the experimentally obtained single-crystal structure. For the atomic charge,
368 we assigned +4e (22 atoms) and +3e (2 atoms) for Ce atoms, and -2e (36 atoms) for O atoms,

369 where 8 O atoms were capped by protons with +1e. Thus, one nanocluster has a total of +30e
370 charges, which was compensated by ligands (-1e for each acid). The charges on Ce atoms were
371 adjusted slightly when the number of ligands was less or greater than 30 to keep the system neutral.
372 These assigned charges on the nanocluster and ligands were reduced by a factor of 0.5 to take
373 account of the screening effect. Otherwise, the unshielded Coulombic interactions between the
374 point charges in the nanocluster and ligands could lead to an unreasonable structure. The universal
375 force field (UFF)⁴⁵ was used to describe the forces involving the ceria nanoclusters. For organic
376 ligands, we used the CHARMM force field, which was generated by the CHARMM-GUI⁴⁶ and
377 then converted into the LAMMPS format by using InterMol⁴⁷. All MD simulations were carried
378 out using the LAMMPS software⁴⁸ with the following steps:

379 1) Minimization by the steepest descent method was followed by NVT (constant number of
380 molecules, volume, and temperature) simulation at 10 K for 10 ps to generate initial velocities.

381 2) Heating the system from 10 K to 563 K over 100 ps using NVT, where the cell volume
382 calculation as a function of the number of benzoic acids (**Fig. 3i**) was performed at 300 K to match
383 the condition of the single-crystal experiment at room temperature.

384 3) NPT (constant number of molecules, pressure, and temperature) production runs at the target
385 temperature for 3 ns, where the Nose-Hoover thermostat and barostat was used with 0.1 ps and 1
386 ps damping times for temperature and pressure, respectively.

387 All initial structures were generated by packmol⁴⁹. VMD⁵⁰ was used for the visualization and
388 analysis of the MD trajectories.

389 **Other characterizations.** TEM images were obtained on a FEI Tecnai Spirit operated at 120 kV.
390 Raman spectroscopy measurements were performed on a Renishaw InViaTM confocal Raman

391 microscope with an Ar⁺ excitation laser wavelength of 514 nm. XPS was carried out using a PHI
392 VersaProbe III equipped with a monochromatic Al K-alpha (1486.6 eV) X-ray source with
393 spherical capacitor energy analyzer to examine oxidation states of the lanthanide elements. Spectra
394 were measured with a 100 μm spot size and 55 eV pass energy. Charging corrections to the binding
395 energy were made by reference to graphitic C 1s at 284.5 eV. Data were analyzed in PHI Multipak
396 9.8.0.19 where a Shirley background was subtracted to remove inelastic scattering components
397 except in the case of Gd, where the Shirley background inappropriately cut off above the
398 background levels. HAADF-STEM images were obtained in an aberration-corrected ‘cubed’
399 Thermo Fisher Scientific Themis Z 60-300 electron microscope operated at 200 kV from EMAT.
400 Thermo Scientific Titan aberration corrected STEM (200 kV) with a Super-X G1 EDS detector
401 were used for STEM-EDS measurement.

402 **Data Availability**

403 The data supporting the finding of the study are available in the paper and its Supplementary
404 Information. Source data are provided with this paper. Crystallographic data for the structure
405 reported in this Article have been deposited at the Cambridge Crystallographic Data Centre, under
406 deposition number CCDC 2157579. Copies of the data can be obtained free of charge via
407 <https://www.ccdc.cam.ac.uk/structures/>.

413 and Scientists, Office of Science Graduate Student Research (SCGSR) program. The SCGSR

414 program is administered by the Oak Ridge Institute for Science and Education for the DOE under
415 contract number DE-SC0014664. This work benefited from the use of the SasView application,
416 originally developed under NSF Award DMR-0520547. SasView also contains code developed
417 with funding from the EU Horizon 2020 program under the SINE2020 project Grant No 654000.
418 This research used resources of the Advanced Photon Source, a U.S. DOE Office of Science User
419 Facility operated for the DOE Office of Science by Argonne National Laboratory, under Contract
420 No. DE-AC02-06CH11357. D.W. acknowledges an Individual Fellowship funded by the Marie
421 Skłodowska-Curie Actions (MSCA) in Horizon 2020 program (Grant 894254 SuprAtom). S.B.
422 acknowledges the support from the European Research Council (Grant No. 815128-
423 REALNANO). The electron microscopy work was performed in part at the Analytical
424 Instrumentation Facility (AIF) at North Carolina State University, which is supported by the State
425 of North Carolina and the National Science Foundation (award number ECCS-2025064). The AIF
426 is a member of the North Carolina Research Triangle Nanotechnology Network (RTNN), a site in
427 the National Nanotechnology Coordinated Infrastructure (NNCI). G. L. gratefully acknowledges
428 the funding support by US NSF (DMR-1752611) and the Dean's Discovery Fund at Virginia Tech.
429 S.D. acknowledges the support from the U.S. DOE, Office of Science, Basic Energy Sciences,
430 Materials Sciences and Engineering Division. P. Bean at the University of Virginia is
431 acknowledged for his SEM contributions measuring the HEASS. We acknowledge T. B. Gunnoe
432 (University of Virginia), J. Elena (University of Virginia), D. E. Jiang (University of California,
433 Riverside), and C. B. Murray (University of Pennsylvania) for the project discussion.

434 **Author contributions:** S.Z. and G.J. conceived and designed the experiments. W.A.G. and
435 M.Y.Y. designed and performed the computational simulations. G.J. and C.L. performed the
436 synthesis and analyzed experimental data with help from B.A. under the supervision of S.Z. and

437 S.D., G.J. and D.A.D. collected and analyzed the SCXRD data. S.W., W.G., D.W. and S.B.
438 performed STEM measurements of the materials. F.P. performed SSNMR experiments. G.J., and
439 C.L. performed *operando* SAXS with assistance from H.Z. and X.Z.. F.M. and C.Z performed
440 MALDI-TOF experiments. Z.X. and G.L. performed TGA experiments. G.J. measured the XPS
441 and Raman spectra. G.J., M.Y.Y., W.A.G., and S.Z. wrote the manuscript. All authors discussed
442 the results and commented on the manuscript.

443 **Competing interests:** Authors declare that they have no competing interests.

444 **Figure Captions:**

445 **Figure 1. Schematic illustration of nanocluster superstructures formation process.** Ceria and
446 other rare earth oxide nanoclusters are assembled into superstructures through an OA-to-BA
447 ligand-switching mechanism at high temperature. By further manipulating surface ligand
448 chemistry, these structures may be disassembled into building blocks with OA and reassembled
449 into superstructures at high temperature with BA. Building blocks may even be combined to form
450 multi-element superstructures with the appropriate ligand treatments.

451 **Figure 2. Superstructure morphology and *operando* SAXS monitoring superstructure**
452 **formation. a-c,** HAADF-STEM images of ceria superstructures show rod-like structures (**a**)
453 generated from the self-assembly of 1.4 nm nanoclusters (**b, c**). **d,** *Operando* SAXS measurements
454 performed at 1-minute intervals show a small shoulder at around $q = 0.2 \text{ \AA}^{-1}$ that is a result of the
455 formation of nanoclusters in solution. This change occurs starting above 260 °C. **e,** Time evolution
456 of the *operando* SAXS profile measured at 290 °C from $t = 0$ minutes when 290 °C is reached.
457 Structure peaks associated with the *bct* superstructure appear at approximately 25 minutes and are
458 indexed in the inset and in Supplementary Figure 3d at $t = 60$ minutes. **f,** $^{13}\text{C} \{^1\text{H}\}$ CPMAS

459 SSNMR of the washed and dried Ceria nanocluster in the pre-assembled, assembled, and
460 disassembled forms. Disassembly was driven by introduction of OA in hexane. The resonances
461 near 40 ppm are due to sp^3 hybridized C atoms while the resonance at 130 ppm indicates sp^2
462 hybridized C in aromatic moieties. **g**, Packing diagram generated from SCXRD of the
463 disassembled Ceria nanoclusters recrystallized in pyridine and acetonitrile. Ce atoms are gold,
464 oxygen atoms are red, and organic components are designated by wire frames.

465 **Figure 3. MD simulations of nanocluster interactions. a, b**, Model structures of OA-packed
466 clusters (**a**) and BA-packed clusters (**b**). Each model contains 2 clusters (Ce: gold, O: red), 60 OAs
467 (sky blue), 60 BAs (magenta), and 120 benzyl ethers (grey), where the BAs in the OA-packed
468 model and the OAs in the BA-packed model were protonated. **c**, The distance between two clusters,
469 where initial cluster-cluster distances were 2.1 nm (blue and red) and 3 nm (sky blue and orange).
470 **d**, The average nonbonding energies (see the Coulombic and van der Waals components in
471 **Supplementary Figures 12 a and b**, respectively) for 3 ns MD simulations ($n = 3$ runs). The
472 energies are presented as the mean values +/- standard deviation (SD). Two models with different
473 initial distances between nanoclusters were used for each system, 2.1 nm (blue and red) and 3 nm
474 (sky blue and orange), respectively. pOA and pBA represent protonated OA and BA, respectively.
475 **e**, Representative edge to face and (**f**) offset π - π interactions between intercluster BA ligands bound
476 to adjacent CeO_x clusters from MD simulations.

477 **Figure 4. Unit cell of the assemblies: size, benzyl ether, and structure. (a)** The change in the
478 cell volume as a function of the number of BAs from MD simulations. The dotted gray line
479 indicates the cell volume of the experimental single-crystal structure. **b**, The cell volume as a
480 function of the number of benzyl ethers incorporated into the superstructure, where the system
481 contains 60 BAs ($n = 3$ runs). Each volume is presented +/- SD. **c**, Snapshot structure showing the

482 unit cell of the self-assembled structure, which is composed of 2 clusters, 60 BAs (purple), and 16
483 benzyl ethers (gray). **d**, $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ core nanocluster. BA ligands (not shown) contribute the
484 remaining oxygens to the nanocluster. H atoms are omitted. Colour Code: Ce^{3+} - green, Ce^{4+} - gold,
485 O^{2-} - red, OH – purple. **e**, BA coated nanoclusters, where dotted lines denote the unit cell. The
486 poorly binding (111) facet opens a pocket for a close approach of the BA from a neighboring
487 nanocluster, forcing alignment in the x direction.

488 **Figure 5. Extended synthesis to other metal oxide superstructures. a-h**, TEM images of LaO_x
489 **(a)**, SmO_x **(b)**, YbO_x **(c)**, HoO_x **(d)**, EuO_x **(e)**, ErO_x **(f)**, TmO_x **(g)**, and GdO_x **(h)** superstructures. **i**,
490 *operando* SAXS measurement of LaO_x self-assembly. A rise at low q ($< 0.05 \text{ \AA}^{-1}$) and a structure
491 peak at $q = 0.407 \text{ \AA}^{-1}$ are apparent at 110 minutes. The feature at $q = 0.5 \text{ \AA}^{-1}$ is an artefact of the
492 measuring geometry and was present at all temperatures.

493 **Figure 6. Multicomponent assemblies. a-d**, TEM images of binary $\text{CeO}_x/\text{LaO}_x$ **(a, b)** and
494 $\text{CeO}_x/\text{SmO}_x$ **(c, d)** superstructures. **e-g**, TEM images **(e,f)**, HAADF-STEM image **(g)** and EDS
495 elemental mapping **(h)**, measured area is indicated in **g** using red frame) of the ternary
496 $\text{CeO}_x/\text{LaO}_x/\text{SmO}_x$ superstructures (mapping colour code: Teal (Ce), Orange (Sm), and Yellow
497 (La)).

19. Supplementary References.

Supplementary Figure 1. Images of the Ceria superstructures. (a) dispersed in hexanes, (b) settled out of hexanes, and (c) dried to a powder. The powder dried sample was weighed to demonstrate the scalability of this synthesis.

Supplementary Figure 2. HAADF-STEM images of Ceria superstructures. HAADF-STEM images of ceria nanocluster assemblies at different magnifications.

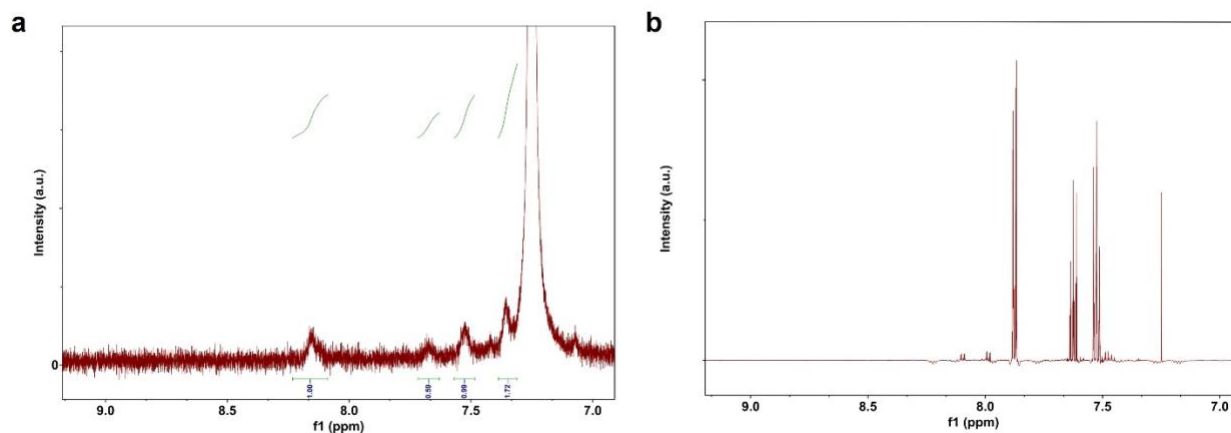

Supplementary Figure 3. Operando SAXS. Schematic illustration of the *operando* SAXS reactor (a) and picture of reactor setup (b) at 12-ID-B beamline at the Advanced Photon Source of Argonne National Lab. The reactor holds up to 15 mL of reactant. Heating tape is wrapped around the reactor with space left open for the X-ray beam. The beam passes through two 0.5 mm windows with 4 mm between them for sample. A condenser is affixed to the top of the reactor and a rubber septum is used to seal the reactor from the atmosphere. (c) A hard sphere model fit of the $T = 290$ °C SAXS profile in Fig. 2d indicates particles with radii of around 0.89 nm have been formed. (d) SAXS profile at $t = 60$ min during *operando* SAXS measurement for monitoring Ceria superstructure formation.

Supplementary Figure 4. ^1H NMR spectra of solvent. (a) Benzaldehyde ^1H NMR signal increases over time while the benzyl ether is heated at 290 $^{\circ}\text{C}$. **(b)** Ratio of the benzaldehyde aldehyde proton to the methylene protons of benzyl ether as measured in ^1H NMR shows an increase of aldehyde as the solvent is held under reaction conditions without Ce precursor at 290 $^{\circ}\text{C}$.

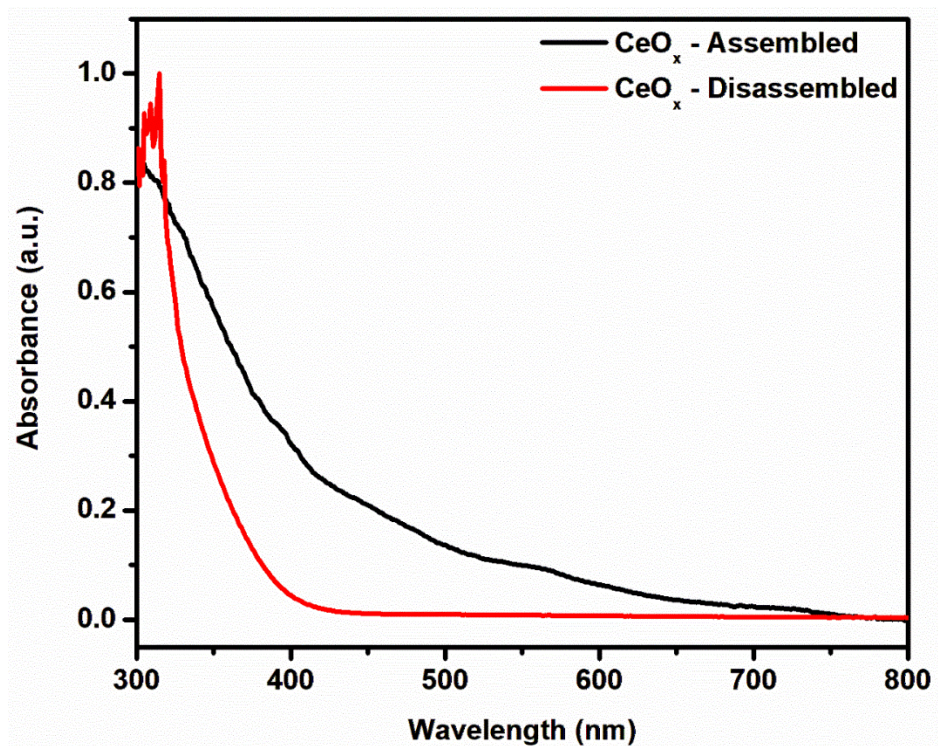

Supplementary Figure 5. BA formation mechanism and Raman spectrum. Proposed mechanism to generate BA from benzyl ether. **(a)** At high temperature, a small amount of benzyl ether decomposes to form benzaldehyde as shown in Supplementary Figure 4. **(b)** This may react through a Cannizzaro type mechanism catalyzed by the metal oxide. The benzyl alcohol formed by this mechanism reacts with benzaldehyde to generate more BA ligands and toluene, which evaporates off. **(c)** Raman spectrum demonstrating chemical signatures of BA moieties on the ceria superstructure sample.

Supplementary Figure 6. ^1H NMR spectra of superstructures. (a) ^1H NMR spectrum of solvated superstructures in CDCl_3 (7.25 ppm) in the region typical of aryl protons. Resonances at 7.52 ppm, 7.68 ppm, and 8.15 ppm are present in a 2:1:2 ratio and correspond to BA. The resonance at 7.36 ppm corresponds with benzyl ether solvent. The absence of a peak at 7.88 ppm (and 10.26 ppm) indicates that benzaldehyde is not present in a significant amount in this sample. (b) ^1H NMR spectrum in the same region of benzaldehyde in CDCl_3 . Major resonances are centered around 7.53 ppm, 7.62 ppm, and 7.88 ppm.

Supplementary Figure 7. Oleic acid dispersed nanoclusters. (a) Golden brown dispersion of Ceria nanoclusters disassembled from superstructure in hexane by adding oleic acid. (b) TEM image of Ceria superstructure treated with oleic acid. The small particles have low contrast with the background and are circled in red to guide the eye.

Supplementary Figure 8. UV-Vis spectra of assembled and disassembled Ceria. UV-Vis spectra of ceria assemblies and disassembled particles.

Supplementary Figure 9. Ceria nanocluster crystal structure with thermal ellipsoids. Nanocluster structure as observed in SCXRD. C atoms are in black, O atoms are red, N atoms are blue, and Ce atoms are yellow. Thermal ellipsoids are set at 50% probability level. CCDC reference number: 2157579.

Supplementary Figure 10. Ceria nanocluster structure with pyridine. Full model of the $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ nanocluster ligated by 30 BAs and 8 pyridines. 4 pyridines directly bind Ce at the (111) facet and 4 interact through H-bonding. Ce atoms are in gold, oxygen atoms are red, BA and pyridine ligands are shown in wire format with N atom bonds of the pyridine highlighted in blue.

Supplementary Figure 11. MALDI-TOF analysis of DMF disassembled Ceria. MALDI-TOF spectrum of DMF disassembled Ceria. The first peak observed in this spectrum is 120 amu above $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8$ and corresponds to a singly deprotonated cluster with a BA ligand. The inset shows how the peaks are subdivided further by 16 amu units. This is assigned to changes in the oxygen numbers of the cluster and may originate either from O loss or dissociation of the BA ligand. The peaks terminate prior to the $\text{Ce}_{24}\text{O}_{28}(\text{OH})_8(\text{BA})_{30}$ maximum of 7580 amu.

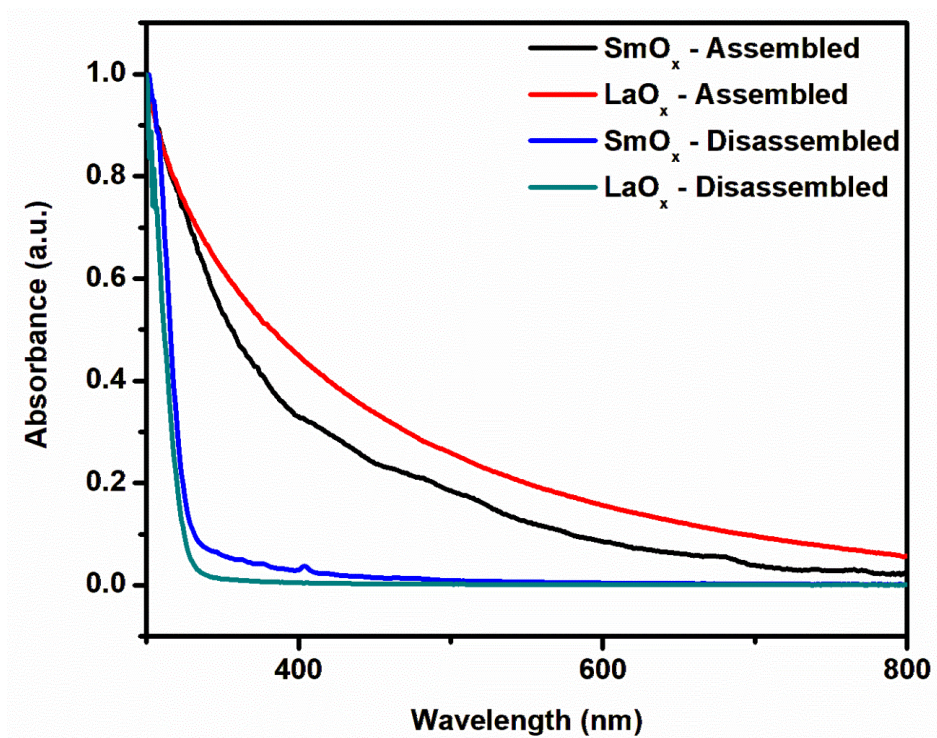

Supplementary Figure 12. Contributions of non-bonding energies. Components of the non-bonding coulombic (a) and van der Waals (b) energies described in **Fig. 3d**. for a 3 ns MD simulation ($n = 3$ runs). Each energy is presented as the mean \pm standard deviation (SD). Two models with different initial inter-cluster distances were used for each system: 2.1 nm (blue and red) and 3 nm (sky blue and orange). pOA and pBA represent protonated OA and BA, respectively.

Supplementary Figure 13. TGA result of Ceria superstructures. The final product is assumed to be $\text{Ce}_{24}\text{O}_{48}$ with a mass of 4154.4 amu due to the treatment in high temperature/ high O_2 conditions. The initial 5.1% weight reduction is assigned to residual solvent on the sample and is neglected for final mass calculations.

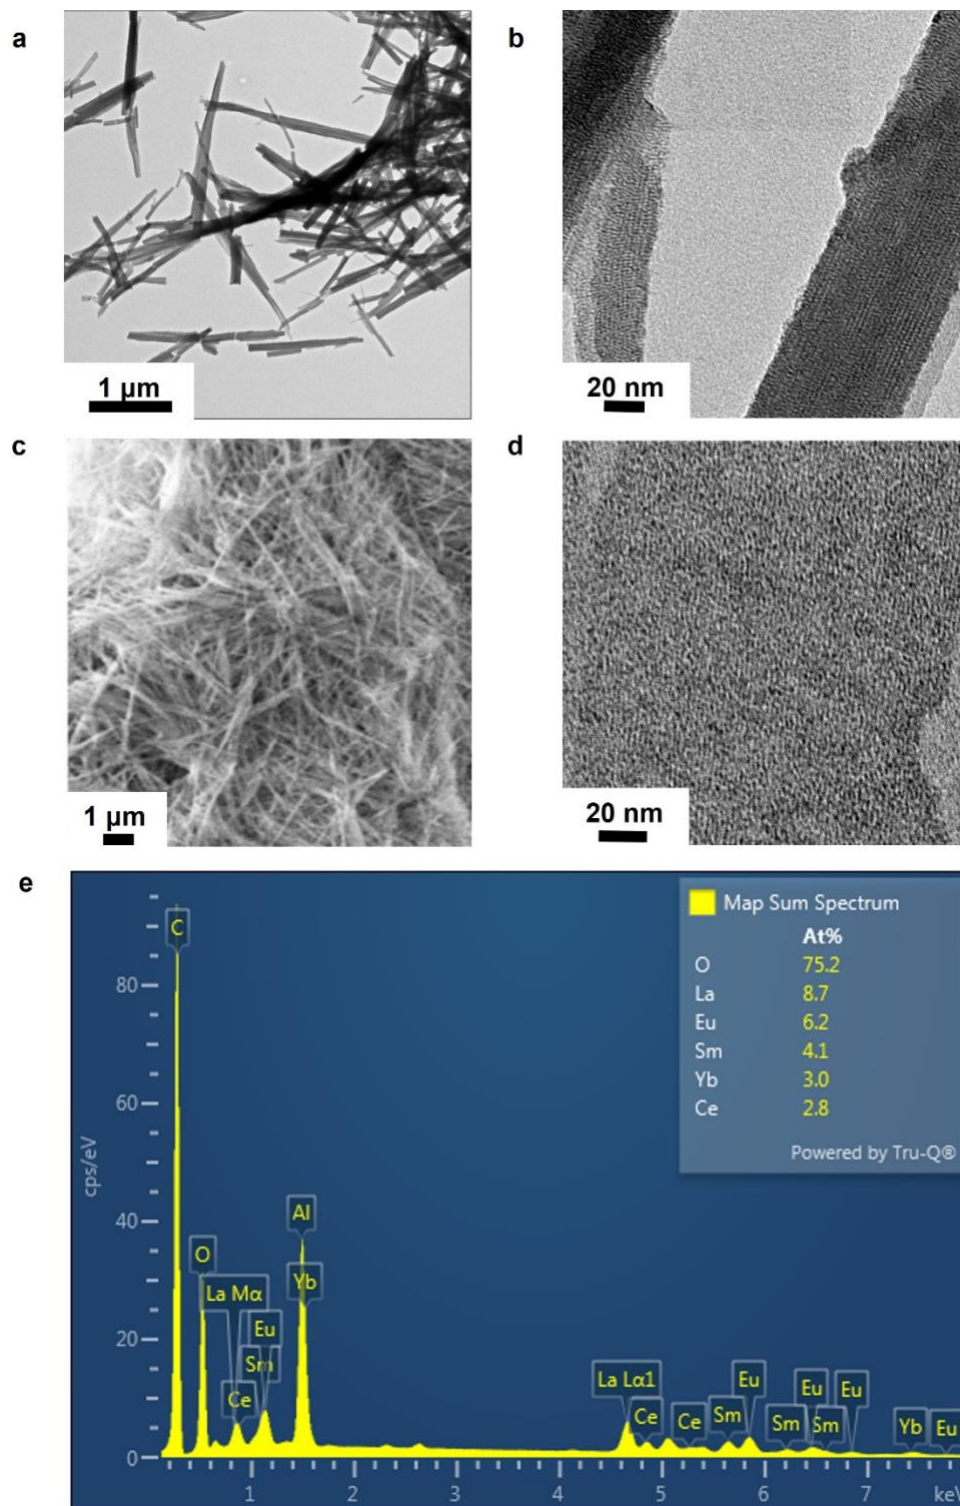

Supplementary Figure 14. Images of other rare earth oxide superstructures. Sample images of EuO_x , YbO_x , ErO_x , HoO_x , TmO_x , GdO_x , LaO_x , and SmO_x .

Supplementary Figure 15. UV-Vis spectra of other rare earth oxides. UV-Vis spectra of SmO_x and LaO_x in both assembled and disassembled states.

Supplementary Figure 16. XPS results of rare earth oxide superstructures. (a) Background subtracted Ce 3d XPS spectrum of Ceria superstructure. Deconvolution of the peaks was performed according to Skala *et al.*¹ This suggests around 80% Ce⁴⁺ content. (b) XPS spectrum of the Tm 4d region. The peak at 176.8 eV agrees with Tm³⁺ in Tm₂O₃ as reported by Aguilar *et al.*² (c) XPS spectrum of the Ho 4d region. The peak at 161.8 eV agrees with Ho³⁺ of Ho₂O₃ reported by Pan *et al.*³ (d) XPS spectrum of the Er 4d region. The peak at 168.7 eV agrees with the previously reported Er₂O₃ value of 168.9 eV.⁴ (e) XPS spectrum of the Eu 4d region shows the 4d_{5/2} peak at 136.1 eV, which is slightly higher than the reported Eu₂O₃ value but agrees with Eu³⁺ in Eu(acac)₃.⁵ This could be a result of the high surface area to volume ratio ligated by carboxylates. (f) XPS spectrum of the Gd 3d region. The signals at 1187.0 eV, 1219.1 eV, and the satellite at 1196.4 eV agree with previous results of Gd₂O₃.⁶ (g) XPS spectrum of the Yb 4d region. The measured value at 185.5 eV and profile agrees with Yb³⁺ in Yb₂O₃.⁷ (h) XPS spectrum of the Sm 3d region. The measured values at 1082.8 eV and 1109.8 eV agree with reported values for Sm₂O₃.⁸ (i) XPS spectrum of the La 3d region and the overlapping La MNN Auger region. The results agree with a La³⁺ with a value of 3d_{5/2} doublet at 834.8 eV and 838.3 eV along with a 3d_{3/2} doublet at 851.6 eV and 855.1 eV.⁹ The split on these doublets, from charge transfer with the O, is 3.5 eV and is smaller than is typically seen with La₂O₃, but is more typical of La₂(CO₃)₃. This could be a result of the high surface area ligated by carboxylate type species.

Supplementary Figure 17. HEAAS. TEM images of the (a) macrostructure and (b) microstructure of Ceria superstructures re-assembled from oleic acid disassembled superstructures. (c) SEM image of the penta-component HEAAS. (d) TEM image showing the assembled structure of the penta-component superstructure. (e) EDS spectrum showing the presence of 5 elements (La, Eu, Sm, Yb, and Ce) used to prepare the superstructures.

Supplementary Table 1: Raman peak comparison. A peak-by-peak comparison of the measured Raman peaks with those reported of sodium benzoate¹⁰.
